(Received 25 October 2004; revised 13 October 2005; accepted 18 October 2005; published online 19 May 2006)

The experimental data on elementary processes (collisional deactivation, chemical reactions, photodissociation) involving spin-orbitally excited X(²P_{1/2}) atoms (X = F,Cl,Br,I) published up to the middle of 2005 are summarized in the present compilation. Critical evaluation of the data and limited comparison to theoretical calculations are also presented. © 2006 American Institute of Physics. [DOI: 10.1063/1.2137724]

Key words: excited atom; halogens; spin-orbital excitation.

1. Introduction

The absence of any review on the properties of spinorbitally excited $X^{*}(^{2}P_{1/2})$ halogen atoms (X = F, Cl, Br, I) in the literature is noteworthy, this fact gave large impetus to the present work. In the present compilation the data on the elementary processes involving X*(²P_{1/2}) atoms published up to the middle of 2005 are presented. For convenience, hereafter the spin-orbitally excited $X^*({}^2P_{1/2})$ will be denoted as X^{*}, and the ground state $X({}^{2}P_{3/2})$ will be denoted as X. The processes fall into the categories:

- (1) collisional deactivation of X*, reactive and nonreactive, at T = 300 K,
- (2) formation of X* atoms in the photodissociation,

- (3) formation of X* atoms in chemical reactions,
- (4) high-energy studies on X^* scattering, and
- (5) exotics, such as collisionally induced transitions between hyperfine levels, or heterogeneous processes.

The main aim of the paper consists in collecting all available experimental data on these processes. Where it is possible, critical evaluation of the data is presented, where special attention is paid to the accuracy of the experimental measurements. In many cases the originally published data may be recalculated and corrected. For example, the X^*/X branching ratio for the products of photodissociation is often determined by REMPI; it may be recalculated by using the best value of the calibration factor. Or, the rate constant obtained by relative measurements may be corrected using the best rate constant of the reference reaction. These corrections have not been done in this paper, almost all the data are presented here like they were originally published by the authors. Usually, the data on the yields of X* atoms in the broadband photolysis are omitted, since they are usually very uncertain; however, in some cases they are presented. The theoretical results are presented very briefly, mainly by references, although some theoretical models are discussed in relation to experimental data where appropriate. To the best of the author's knowledge, in the literature there are no reviews on the chemical properties of X* atoms except very early papers.^{1–5}

In this paper, the collisional deactivation of X^* atoms is characterized by the rate constants at T=300 K. These constants usually do not differentiate between chemical reaction and physical quenching of X^* atoms. Only in some cases are the branching ratio between the probabilities of reactive and nonreactive pathways or the temperature dependencies of the rate constants available; this rare information is presented usually in footnotes or in comments.

The relative yield of X^* atoms in photodissociation processes is characterized by the branching fraction

$$\Gamma = \frac{[X^*]}{[X^*] + [X]} = \frac{[\sigma^*]}{[\sigma^*] + [\sigma]},$$
(1)

where $\sigma^* = \sigma(X^*)$ and $\sigma = \sigma(X)$ are the cross sections for the production of excited and ground state atoms, respectively; [X] and [X*] denote concentrations of these atoms. Note that excited ${}^{2}P_{1/2}$ and ground ${}^{2}P_{3/2}$ levels contain two and four M_J electronic sublevels, respectively; hence in the case of $\Gamma = 1/3$ the populations of X* and X are equal.

For a one-photon electric dipole transition the c.m. angular distribution of X^* atoms produced in photodissociation is given by^{6–8}

$$f(\theta) = 1 + \beta P_2(\cos \theta), \qquad (2)$$

where θ is the angle between the electric field vector (e) of the dissociating light and the recoil direction (v) of the photofragment, and $P_2(x) = (3x^2 - 1)/2$ is the second Legendre polynomial. The anisotropy parameter β describes the spatial distribution of X* atoms and has a value between -1 [e \perp v, perpendicular transition, $f(\theta) = (3/2)\sin^2 \theta$] and 2 [e||v, parallel transition, $f(\theta) = 3 \cos^2 \theta$]. The β parameter can be related to the angle (χ) between the direction of the transition dipole in the molecule and the recoil direction by

$$\beta = 2\kappa P_2(\cos\chi), \tag{3}$$

where $0 \le \kappa \le 1$ is a parameter that takes into account any decrease in the observed β due to rotational, vibrational, and translational motion of the parent molecule. Usually the largest contribution to κ comes from rotational motion.⁹ It may be estimated as⁸

$$\kappa = \frac{1+\eta^2}{1+4\eta^2},\tag{4}$$

where η is the angle between the recoil velocity vector that would result if the molecule was not rotating and the vector that actually results. If the dissociation process is fast relative to rotation of the parent molecule, then the factor κ is equal to unity (η =0). In this case, the β parameter may be reduced due to the thermal motion of the parent molecule by the factor¹⁰

$$\kappa = 1 - 3kT/\sqrt{2}E_t, \tag{5}$$

where E_t is the thermal energy of parent molecule, $kT \ll E_t$ is assumed.

In this paper, the yield of X^* atoms in photodissociation is characterized by Γ and β parameters. Only in several outstanding cases (like HI, ICN, or CH₃I) does there exist experimental information in addition to these parameters; this information is presented briefly in footnotes or in comments. The production of X* atoms in chemical reactions is usually characterized by the branching fraction Γ . The results of high-energy studies on the X* scattering are characterized by collisional cross sections.

In large tables of this paper, molecules—precursors of X^* atoms or collisional partners of X^* atoms—are listed in the order of increasing number of atoms in the molecule. The molecules with equal number of atoms are listed in the order of increasing mass. The results on each molecule are presented in chronological order.

1.1. Spin-Orbit Splittings and Radiative Lifetimes

The mean radiative lifetime τ_e for the spin-orbitally excited state ${}^{2}P_{1/2}$ is given by

$$1/\tau_e = A({}^2\mathrm{P}_{1/2} \rightarrow {}^2\mathrm{P}_{3/2}) = \frac{2(\Delta E)^3 \mu^2}{3\hbar^4 c^3},$$
 (6)

where μ is the reduced matrix element of the magnetic dipole operator

$$\mu^{2} = 3 \sum_{M'_{J},M''_{J}} |\langle^{2} \mathbf{P}_{1/2,M'_{J}} | \mu_{z} |^{2} \mathbf{P}_{3/2,M''_{J}} \rangle|^{2}.$$
(7)

Here, a magnetic dipole transition between ${}^{2}P_{1/2}$ and ${}^{2}P_{3/2}$ states is assumed, μ_{z} is the z component of the magnetic dipole operator, and $\Delta E = E({}^{2}P_{1/2}) - E({}^{2}P_{3/2})$ is the spin-

^aCalculated with Eq. (6).

 ${}^{b}\Delta E$ is equal to 882.35283(23) cm⁻¹ and 882.35367(23) cm⁻¹ for 35 Cl and 37 Cl, respectively.¹⁵ See previous values in three studies.^{27–29}

^cThe ratio $\tau_e(Cl)/\tau_e(I)$ was measured, $\tau_e(I) = 0.125$ s reported by Engelman *et al.*²³ was assumed.

^dSeveral previous values are presented.^{2,25,30}

eRelativistic calculation using Dirac-Fock-Breit calculation.

^fExtensive review on all previous values are presented by Ha *et al.*,²⁶ in this table only values obtained after 1980 are presented in chronological order. ^gMulticonfiguration Hartree–Fock calculation.²⁶

orbital splitting. In Russell–Sanders *L-S* coupling approximation $\mu_z = \mu_B(L_z + g_e S_z)$ and the reduced matrix element may easily be calculated as

$$\mu^2 = \frac{4}{3}(g_e - 1)^2 \mu_B^2, \tag{8}$$

where g_e is the electron spin gyromagnetic ratio $(g_e = 2.00232)$, $\mu_B = e\hbar/2m_ec$ is the Bohr magneton, and L_z and S_z are the *z* components of the operators **L** and **S**, the electron angular and spin momenta, respectively. The spinorbit splittings, the latest experimental values of τ_e , and the values of τ_e calculated with Eqs. (6)–(8) are summarized in Table 1.

The contribution of the electric quadrupole moment to the overall transition probability in the iodine atom has been determined from the experimental ratio S(J=1/2,F=2) $\rightarrow J=3/2,F=4)/S(J=1/2,F=3) \rightarrow J=3/2,F=4)=0.0035$,

where *S* denotes the strength of the absorption line. From these data the contribution of the electric quadrupole moment may be calculated to be 0.52%.²⁶

The validity of the *L-S* approximation has recently been confirmed by He *et al.*,¹⁸ in which a theoretical calculation for the magnetic dipole transition moment in Br atoms was carried out using a relativistic Dirac–Fock–Breit *ab initio* atomic structure formulation. The theoretical value was in excellent agreement with the value predicted assuming *L-S* coupling (see Table 1). *Ab initio* calculations of expression (7) using a multiconfiguration Hartree–Fock level program were done by Ha *et al.* for transitions in the iodine atom.²⁶ The calculations gave the result $\tau_e = 0.165$ s, which is in

moderate agreement with experiment and the result of the simplest analytical *L-S* coupling model, $\tau_e = 0.126$ s.

Note that for a given element in the single electron approximation the ΔE splitting is proportional to the reduced mass of the electron-nucleus pair.²⁹ Hence the difference in ΔE for different isotopes of Cl and Br may easily be calculated.

1.2. Hyperfine Structure

The hyperfine structure Hamiltonian for a halogen atom can be written as $^{31-35}$

$$H_{hfs} = a_J H^D + b_J H^Q + c_J H^O, \qquad (9)$$

$$H^D = \mathbf{I} \cdot \mathbf{J},\tag{10}$$

$$H^{Q} = \frac{3(\mathbf{I} \cdot \mathbf{J})^{2} + (3/2)(\mathbf{I} \cdot \mathbf{J}) - I(I+1)J(J+1)}{2I(2I-1)J(2J-1)}, \quad (11)$$

where H^D , H^Q , and H^O are the operators for magnetic dipole, electric quadrupole, and magnetic octupole interactions, respectively; a_J , b_J , and c_J are the constants of these interactions, respectively. **J** is the total electron angular momentum (**J**=**L**+**S**, *L*=1, *S*=1/2, *J*=1/2,3/2), **I** is the nuclear spin, and **F** is the total angular momentum (**F**=**J**+**I**). Note that for the upper state of the fine structure (*J*=1/2) the second and the third terms in Eq. (9) are equal to zero. The energy levels of the atom may conveniently be obtained from Eq. (9) as^{31,32,35-37}

$$E_{JF} = a_J C/2 + b_J \frac{(3/4)C(C+1) - D}{2I(2I-1)J(2J-1)} + c_J \{C^3 + 4C^2 + 4C[J(J+1) + I(I+1) + 3 - 3D]/5 + 4D\},$$
(12)

where C = F(F+1) - I(I+1) - J(J+1) and D = I(I+1)J(J+1).

Because of large spin-orbital splitting, the J=1/2 and J=3/2 levels only perturb each other to a very small extent. For given *F*, matrix elements of the H^D operator are nondiagonal with respect to *J*. The off-diagonal terms are proportional to the additional $a_{1/2,3/2}$ coupling constant

$$\langle I, M_I, J, M_J | H^D | I, M_I, J - 1, M_J \rangle = a_{J-1,J} M_I (J^2 - M_I^2)^{1/2}.$$
(13)

Note that $a_{3/2}$, $a_{1/2}$, and $a_{1/2,3/2}$ are often denoted as a', a'', and a''', respectively. These constants may be estimated using simple theory as^{33,38} $a_{3/2} = -15g_I \mu_B^2 \langle r^{-3} \rangle / 15$, $a_{1/2,3/2} = -a_{3/2}(5-16\beta')/[16(1+\beta')]$, and $a_{1/2} = 5a_{3/2}$, where g_I is the nuclear g factor, β' is a small fractional contribution by s electrons to the measured $a_{3/2}$ constant,^{39,40} and $\langle r^{-3} \rangle$ is taken over the 2p wave function. The $a_{1/2,3/2}$ constants have been determined experimentally for fluorine^{14,40} and chlorine.⁴¹

The parameters for expressions (9), (12) for the halogen atoms are listed in Table 2. The constants a_J , b_J , and c_J may be determined from experimental data with or without the second-order correction Eq. (13). In Table 2 the contri-

^cThe values calculated from data of Braun *et al.*¹⁵ are 882.362931 and 882.362099 cm⁻¹ for ³⁵Cl and ³⁷Cl, respectively.

 ${}^{d}\Delta E_{F',F''} = E_{1/2,F'} - E_{3/2,F''}$, quantum numbers F' and F'' are shown in brackets.

bution from these off-diagonal terms is taken into account. The uncorrected constants for I and Br may be taken from papers of King and Jaccarino³⁷ and Brown and King,³⁵ respectively. In X^*-X absorption spectra the strongest component is the $(J=3/2, F=I+3/2) \rightarrow (J=1/2, F=I+1/2)$ line. In the last column of Table 2 the energies of these strongest transitions are presented.

1.3. Detection Methods

1.3.1. Detection Methods: Summary, Abbreviations, and Sensitivities

A number of methods have been applied to detect the X* atoms, they are summarized in Table 3. The second column of the table gives the abbreviations for detection methods which are used through all this paper. These abbreviations may consist of three parts: the first one denotes the detection method, the second denotes spectral region ("IR," "VIS," "UV," and "VUV" mean infrared, visible, ultraviolet, and vacuum ultraviolet, respectively), and the third shows which particle is detected ("CP," "PF," "PP," "RP," and "CP PF" mean collisional partner, photofragment, photolysis products, reaction product, and collisional partner of photofragment, respectively). If the particle is not mentioned, it usually means direct detection of X* atoms. In the table all indirect detection methods are shown by italic letters, but it does not mean that they are less reliable than direct methods. For example, direct detection of A atoms in the photodissociation of a diatomic AX molecule is often even more informative than direct detection of X* or X atoms. The third column of the table gives the wavelength for the detection methods, the wavelength for the strongest line is presented. The column is normally empty for nonoptical and for indirect methods.

Modifications of the detection methods may be shown; we denote all REMPI-based ion imaging methods, ^{52,53} including the velocity mapping variant of the technique as REMPI/I, LMR/S means the fast-magnetic-field-jump version of time-resolved laser magnetic resonance, ^{54,55} SE IR/SS means steady-state infrared spontaneous emission, ⁵⁶ and notation REMPI is used instead of REMPI (2+1).

Typical sensitivities of several detection methods are summarized in Table 4. The sensitivities of several recent methods continue to increase. For example, in the early experiments, Arepalli *et al.* reported the detection limit for REMPI (2+1) as $[Br^*]_{min}=10^{10}$ cm⁻³.⁹⁸ According to Ashikhmin *et al.*, this sensitivity is limited mainly by the dimension of the probed volume.¹⁰⁰ For example, if the probe volume is 0.04 mm³, the probability of ionization of X* atom in the volume is 0.25, and the detection limit is 25 ions per pulse, then the sensitivity of REMPI detection becomes $[Br^*]_{min} = 2.5 \times 10^6$ cm⁻³.¹⁰⁰

However, for the modern REMPI ion imaging methods the probability of ionization may be increased up to unity, and the detection limit is one ion per pulse; hence the sensitivity may be two orders of magnitude higher.

1.3.2. Calibration Factors for REMPI Detection

REMPI (2+1) is the most popular method for studying photodissociation dynamics. However, there has been some uncertainty in the intensity factors relating the strengths of the REMPI signals to the ${}^{2}P_{1/2}$ and ${}^{2}P_{3/2}$ spin-orbit states. The transitions in halogen atoms, which are usually used for REMPI detection, are collected in Table 5.

Generally, the calibration factor is the ratio of the transition probabilities for REMPI transitions in atoms A and B, these probabilities are denoted here as $P_A(\lambda_A)$ and $P_B(\lambda_B)$, where λ denotes the corresponding wavelength of radiation. The calibration factor is usually used as

$$\frac{[A]}{[B]} = \frac{P_{B}(\lambda_{B})}{P_{A}(\lambda_{A})} \frac{S_{A}}{S_{B}},$$
(14)

where [] represents the corresponding number density, and S_A and S_B are line strengths of the REMPI signals of A and B atoms, respectively. The calibration factors for halogen atoms are presented in Table 6 in chronological order for each atom.

In several early studies of Kawasaki and co-workers^{189–191} the ratio $P_{\rm Cl}(235.336)/P_{\rm Cl}*(237.808)$ was assumed to be unity based on the theoretical approach of Pindzola¹⁹² in which only $\Delta S = 0$ transitions were taken into account. In reality $\Delta S > 0$ transitions contribute strongly to the REMPI

^aIn the table, the detection methods are listed in chronological order for each atom. The abbreviations (listed in alphabetical order) are:

AKS VUV=absorption kinetic spectroscopy of Br* atoms in the vacuum ultraviolet.

ARA=atomic resonance absorption.

ARF=atomic resonance fluorescence.

AS=absorption spectroscopy.

 $AS-DL=diode\ laser\ absorption\ spectroscopy\ (I^*-I\ is\ usually\ detected\ by\ an\ InGaAsP\ diode\ laser.)$

AS-FCL=F-color-center laser is used for Br*-Br absorption spectroscopy.

Br-laser=study of photodissociative Br*-Br laser threshold gain, the relaxator is added in the active medium of the laser.

CARS=time-resolved polarized coherent anti-Stokes Raman spectroscopy of Cl* atoms.

CT PP=chemical trapping of I* atoms. Analysis of photolysis products.

DI=a combination of one-dimensional Doppler technique with a two-dimensional imaging technique was used to detect H atoms from the photodissociation of HBr.

EPR=electronic paramagnetic resonance.

Fl VUV=resonance fluorescence of excited Cl* atoms.

Fl IR=infrared fluorescence of vibrationally excited molecules.

Fl IR CP PF=infrared fluorescence of vibrationally excited collisional partners of photofragments. (For example, HBr+ $h\nu_{\rm UV}$ \rightarrow Br*/Br+H*,

H*+AB \rightarrow H+AB*, AB* \rightarrow AB+ $h\nu_{IR}$, where H* denotes translationally "hot" atoms.)

FMDS=transient frequency-modulated Doppler spectroscopy.

GC PP=gas chromatography of photolysis products.

HR-TOF=detection of H atoms by high-n Rydberg time-of-flight technique.

ICS=intracavity spectroscopy based on a pulsed photodissociative I*-I laser.

I-laser=study of photodissociative I*-I laser threshold gain, the relaxator is added in the active medium of the laser.

LIF=laser induced fluorescence.

LIF-DS=LIF Doppler spectroscopy (of H atoms).

LMR=laser magnetic resonance of Cl* atoms (¹³CO₂-laser).

LOAT=laser optoacoustic technique.

Lum RP=detection of the luminescence of excited I_2^* arising in the recombination $I^*+I \rightarrow I_2 + h\nu$.

MCD=magnetic circular dichroism.

MS PP=mass spectrometry of photolysis products.

REMPI (n+m)=resonance-enhanced multiphoton ionization, number of photons is shown in brackets.

SE IR=spontaneous ${}^{2}P_{1/2} \rightarrow {}^{2}P_{3/2}$ emission in the infrared.

SE VIS RP=spontaneous emission in visible wavelength range of excited reaction products $(I^*+I \rightarrow I_2^*, I_2^* \rightarrow I_2 + h\nu)$.

TOF-MS=time-of-flight mass spectrometry.

TP-LIF=two-photon laser induced fluorescence.

TR-MS PP=time-resolved mass spectrometry of photolysis products.

TR-SM=time-resolved spectrometry.

^b206.2 nm and 178.2 nm are the excitation and fluorescence wavelengths, respectively.^{131,148}

signals. Later Kawasaki and co-workers have measured the ratio and obtained the value of 2.5.^{175,193} The value for the ratio $P_{\rm Cl}(235.336)/P_{\rm Cl*}(235.205)$ was determined several times to be 1.25,¹⁷⁶ 0.85,¹⁷⁷ 1.11,¹⁷⁸ 1.17,¹⁷⁹ and 1.06.¹⁸⁰ The value of Liyanage *et al.*¹⁷⁷ is mentioned briefly as a footnotes and probably is less reliable, all other values are in rather good agreement. Note also, that the theoretical calculations of the calibration factors are rather accurate, they may be used to choose the most reliable factors.^{176,179}

It is useful to mention that two-photon laser induced fluorescence (TP-LIF) uses the same two-photon transitions as REMPI does. For example, the I* and I atoms may be probed by TP-LIF at 306.73 nm $[6p {}^{2}D_{3/2} \leftarrow 5p {}^{2}P_{1/2}]$ and 304.67 nm $[6p {}^{2}D_{5/2} \leftarrow 5p {}^{2}P_{3/2}]$, respectively. The TP-LIF calibration factor $P_{1*}(306.73)/P_{1}(304.67)$ was obtained by Das *et al.*^{194–196} to be 1, and by Brewer *et al.*¹³¹ to be 1.12. However, the same calibration factor for REMPI detection of iodine atoms is another, it is equal to 1.63.¹⁸⁵ Hence the calibration factors for REMPI and for TP-LIF may be different.

1.4. Lasing System

The development of infrared lasers employing the ${}^{2}P_{1/2} {}^{-2}P_{3/2}$ transition of halogen atoms strongly stimulated the study of the chemical properties of these atoms.^{197,198} A review of these lasers is not a purpose of the present paper, and hence only a brief summary, mainly of chemical interest, will be given here.

1.4.1. Chlorine Laser

A photodissociative-chemical repetitively pulsed laser operating on the Cl^{*}-Cl transition was created in 1986.¹⁹⁹ The major steps in the kinetic scheme of the laser are as follows:

$$ICI + h\nu \rightarrow I^*/I + CI^*/Cl, \qquad (15a)$$

$$I^* + ICI \rightarrow Cl^* + I_2, \qquad (15b)$$

Atom	Upper state	λ (nm)

I*	$({}^{1}D_{2})6p([1]_{1/2})^{e}$	277.40 ^{172,173}
	$({}^{1}D_{2})6p([3]_{5/2})$	281.73 ^{172,173}
	$({}^{3}P_{1})6p([1]_{1/2})^{e}$	304.03 ^{172,173}

^aNo assignment.

^bThe upper state is a mixture of a ${}^{2}P_{1/2}$ and a ${}^{2}S_{1/2}$ states.

^cAccording to Rakitzis *et al.*, the upper state is $5p({}^{2}P_{1/2})$.¹⁶⁹

^dDifferent assignments have been proposed: $Br \rightarrow 2S_{3/2}$, 98,102 Br $\rightarrow 4p(^4(^{3}P), 5p(^{4}D_{7/2}), ^{165}$ and $Br^* \rightarrow 2P_{3/2}$.

^eAccording to Kang *et al.*,¹⁷¹ at 277.38 and 304.02 nm the intermediate states are $({}^{3}P_{0})6p([1]_{3/2})$ and $6p({}^{4}D_{1/2})$, respectively.

$$Cl+ICl \rightarrow I+Cl_2$$
, (15c)

$$Cl^* \rightarrow Cl + h\nu.$$
 (15d)

The first step Eq. (15a) is a broadband photolysis of ICl. It produces a population inversion on the Cl*-Cl transition at the wide range of wavelengths, 225–530 nm (see Table 10). Moreover, a high quantum yield of I* atoms also occurs at 248–404 nm (see Table 19). The second step Eq. (15b) is a chemical reaction which transfers the spin-orbital excitation from iodine to chlorine atoms. The yield of Cl* from the I*+ICl reaction has been determined by Nadkhin *et al.*²⁰⁰ (\geq 70%) and by Sotnichenko²⁰¹ (60% ± 15%). Formation of Cl*+I₂ is found to account for 63% ± 17% of the overall TABLE 6. Calibration factors for REMPI detection of halogen atoms

^aARA IR detection of Cl* and Cl in photolysis of HCl.

^bLIF VUV detection of Cl* and Cl in photolysis of HCl.

^cREMPI detection of Cl* at 237.808 nm and Cl at 237.73 and 235.336 nm. The ratio $P_{Cl}(235.336)/P_{Cl}*(237.808)=2.5^{175}$ was used.

^dTwo methods: theoretical calculation and REMPI detection of Cl*.

^eCalculated from R_1 and R_2 , where $R_1 = P_{Cl*}(235.205)/P_{Cl*}(237.808)$ and $R_2 = P_{Cl}(235.336)/P_{Cl*}(237.808) = 2.5$.¹⁷⁵ The ratio R_1 was determined by REMPI detection of Cl*.¹⁷⁸

^fHR-TOF detection of H atoms in photolysis of HCl.

^gThe value and the measurement of the calibration factor are not described. ^hTOF-MS of NO in photolysis of BrNO.¹⁸⁷

ⁱTOF-MS of Br* and Br in photolysis of Br₂.

^jThe measurement of the calibration factor is not described.

^kTOF-MS of Cl*, Cl, Br*, and Br in photolysis of BrCl.

¹REMPI detection of I^{*} and I in the photolysis of I₂ near 304 nm. Only I₂ \rightarrow I^{*} + I channel is assumed.

^mThe yield of I* in the photolysis of CH₃I have been compared with that studied by TOF-MS¹⁸⁸ and SE IR.¹³⁷

rate of the deactivation of I* by ICl;^{200–202} the rate constant for the overall I*+ICl deactivation is $(2.4\pm0.9)\times10^{-11}$ cm³/molecule·s.^{56,203,204} The third step Eq. (15c) is a chemical removal of ground state chlorine atoms, the rate of this reaction is 8×10^{-12} cm³/molecule·s.^{75,77,83,205,206} It is 33 times larger than the rate of deactivation of Cl* by ICl.^{77,83,206} The advantages of this laser are simplicity and quick restoring of working gas after the laser pulse.²⁰⁷ Since ICl absorbs well in a spectral region of maximum solar radiation, this chlorine laser based on the photodissociation of ICl is interesting because it may be pumped

by solar radiation. Later, this Cl*-Cl laser was applied by Sotnichenko *et al.* for study of collisional quenching of Cl*.^{75,208}

Also, the inversion population on the Cl^{*}-Cl transition was observed in microwave and radio-frequency discharges in ICl/Ar mixtures.²⁰⁹ The density of the population inversion was about 2×10^{12} cm⁻³ for both kinds of discharge. This value is not enough to create a continuous wave laser.

1.4.2. Bromine Lasers

In spite of the large number of molecules which produce population inversion on the I*-I transition in photodissociation processes there are only several molecules (see Table 13), which give population inversion on this transition in the bromine atom. The lasing action on the Br*-Br transition was first observed by Guiliano and Hess in 1969,²¹⁰ who used flash photolysis of gaseous IBr. Later, the Br*-Br laser emission has been observed during flash photolysis (190-225 nm) of CF₃Br by Campbell and Casper.⁴⁷ Efficient, repetitively pulsed Br*-Br lasers driven by photodissociation of static IBr or Br₂ samples were proposed,²¹¹⁻²¹³ where broadband flash photolysis was used, and later by Pastel et al. who pumped the bromine laser by radiation of a Nd:YAG laser with $\lambda = 532$ nm.¹⁹⁷ The kinetic scheme for IBr laser coincides in all details with that for ICl laser [Eqs. (15a)-(15d)]. As chlorine laser based on photodissociation of ICl, this bromine laser may also be pumped by solar radiation. Usually the energy efficiency of these Br*-Br lasers are much smaller than that of iodine I^*-I lasers.

Note that continuous Br*-Br lasers have never been created.^{198,213-215} According to Boriev and Gordon,^{216,217} the problem is connected with vibrationally excited IBr:

$$\operatorname{IBr} + h \nu \rightarrow \operatorname{IBr}^*$$
, (16a)

$$IBr^* + IBr \rightarrow 2IBr^*(v < 40), \tag{16b}$$

$$Br^* + IBr^*(v < 7) \rightarrow I^* + Br_2, \qquad (16c)$$

$$I^* + IBr \rightarrow Br^* + I_2, \qquad (16d)$$

where the first step (16a) is photoexcitation of IBr, the second step (16b) is collisional production of vibrationally excited IBr*, and the last two steps are the chain decomposition of IBr.

The population inversion on the Br^*-Br transition may be used to create different infrared lasers pumped by electronic-vibrational (*E*-*V*) energy transfer from Br^* atoms,

$$Br^* + M \rightarrow Br + M^{**}$$
 (17a)

$$\mathbf{M}^{**} \to \mathbf{M}^{*} + h\,\nu, \tag{17b}$$

where M* and M** denote vibrationally excited M molecules, the inversion population is created on the M**-M* transition which has the energy $h\nu$.²¹⁸ Infrared lasers pumped by the *E*-*V* energy transfer from Br* to CO₂, N₂O, HCN, H₂O, and C₂H₂ are reported by Leone *et al.*²¹⁹⁻²²¹ In these studies, gas mixtures containing excited Br* atoms were prepared by flash photolysing Br₂ in the presence of a polyatomic molecule. The ensuing *E*-*V* process is selective and pumps the polyatomic molecule into specific energy states. In addition to obtaining gain and/or stimulated emission at CO₂ and N₂O laser frequencies, stimulated emission from HCN at 3.85, 7.25, and 8.48 μ m, and from C₂H₂ in the region 7–8 μ m have been obtained.²¹⁹ Wittig and co-workers constructed a 5.3 μ m laser which they attributed to the NO ($v=2\rightarrow v=1$) transition pumped by Br*+NO collisions.²²² The inverted vibrational distribution of excited NO ([NO(v=2)]/[NO] \approx 0.84) was confirmed later by Wight.²²³

The dynamics of a Br^{*}-Br pulsed laser and a Br^{*}-NO ($v=2 \rightarrow v=1$) transfer laser driven by photolysis of IBr was later studied by Johnson *et al.*²²⁴ A CO₂ laser operating on the 10(0)1-10(0)0 transition at $\lambda = 4.3 \ \mu$ m and pumped by *E*-*V* energy transfer from Br^{*} has been demonstrated recently by Johnson *et al.*²²⁵ This laser was driven by photolysis of IBr or Br₂ by a frequency-doubled Nd:YAG laser or Ar⁺ laser, respectively. The output energy and gain of this laser is adversely affected by rapid vibrational *V*-*V* relaxation of CO₂ molecules.

1.4.3. lodine Lasers

The atomic iodine photodissociation laser was created in 1964 by Kasper and Pimentel, who have observed a spontaneous emission from the UV photolysis of CF_3I and CH_3I .²²⁶ The emission was interpreted as the generation due to

$$CX_3I + h\nu \rightarrow CX_3 + I^*, X = H,F,$$
 (18a)

$$I^* \to I + h \nu_0, \quad \lambda_0 = 1.316 \ \mu \text{m.}$$
 (18b)

Later the laser emission was obtained from the photolysis of the other alkyl iodides, and as most efficient compound i-C₃F₇I was found.^{227,228} Since then, the iodine laser has been studied intensively.^{229–231} For example, it was found that additional chemical generation of the population inversion on the I*–I transition comes from the reaction CF₃* + CF₃I \rightarrow C₂F₆+I*, where CF₃* denotes excited radicals, or indirectly in the reaction CF₃+I \rightarrow CF₃I, which removes the ground state iodine atoms.^{232,233}

Later Derwent and Trash²³⁴ suggested that a I*–I laser could be constructed based upon the following energy-transfer equilibrium

$$O_2(a^{1}\Delta_g) + I \leftrightarrow O_2(X^{3}\Sigma_g^{-}) + I^*, \qquad (19)$$

since $O_2(a^{1}\Delta_g)$ is extremely metastable with respect to both spontaneous radiation (half-time ~45 min)^{235,236} and collisions (typically 10⁶ collisions are required); the rate constants of direct and reverse reactions [Eq. (19)] are fast, they are equal to $(7.6\pm2.5)\times10^{-11}$ and $(2.6\pm0.9)\times10^{-11}$ cm³/molecule·s, respectively.²³⁷ The chemical oxygen–iodine laser (COIL) was discovered, when the chemical generation of a population inversion between the spin-orbit states of atomic iodine was observed by Pritt *et al.*²³⁸ The first continuous wave COIL was developed by McDermott *et al.* in 1978,²³⁹ since then the COIL technology has undergone numerous improvements^{240–242} and chemical efficiencies as high as 27%–30% using helium diluent have been demonstrated;²⁴³ now multikilowatt lasers are routinely constructed.^{244–247}

Much of the development of the iodine laser technology to date has focused on a new generator of $O_2({}^1\Delta)$. One approach is to provide the necessary atomic iodine and $O_2({}^1\Delta)$ purely by electrical discharge.^{248–252} It has been found by Ivanov *et al.* that excitation of molecular oxygen in a glow discharge at around 1 Torr provides significant concentrations of $O_2({}^1\Delta)$, up to 2×10^{15} cm⁻³.²⁴⁹ Researchers in Japan have demonstrated very large yields of the $O_2({}^1\Delta)$ precursor molecules, up to 32%, using a microwave and rf discharges in the mixtures of O_2 , N_2 , NO, and NO₂; it was demonstrated that added gases increased the yield of singlet oxygen.^{250,251}

Another, and very promising, approach is replacement of singlet oxygen with chemically generated nitrene metastables such as NCl($a^{1}\Delta$) or NF($a^{1}\Delta$). This approach led to an all gas-phase iodine laser, it eliminates the heavy, water-based COIL chemistry based on very corrosive hydrogen peroxide. In 1995, Ray and Coombe created a pulsed I*–I laser pumped by energy transfer from NCl($a^{1}\Delta$); the iodine atoms and NCl were produced by photodissociation of CH₂I₂ and ClN₃ at 193 nm.^{253,254} Excited NCl($a^{1}\Delta$) molecules exchange energy with atomic iodine in a manner analogous with oxygen in COIL

$$\mathrm{NCl}(a^{1}\Delta) + \mathrm{I} \rightarrow \mathrm{NCl}(X^{3}\Sigma^{-}) + \mathrm{I}^{*}, \qquad (20)$$

with the rate constant of 2×10^{-11} cm³/molecule s.²⁵⁵ Using an optical double-resonance technique, Yang *et al.*²⁵³ have observed a population inversion between the ${}^{2}P_{1/2}$ and ${}^{2}P_{3/2}$ states of atomic iodine, produced in this reaction. Recently, Henshaw *et al.*^{256,257} developed the all gas-phase iodine laser based on the energy transfer process (20), where reactions of Cl with HN₃ were used for the generation of excited nitrogen chloride:

$$Cl+HN_3 \rightarrow HCl+N_3$$
, (21a)

$$\operatorname{Cl} + \operatorname{N}_3 \to \operatorname{NCl}(a^{1}\Delta) + \operatorname{N}_2.$$
 (21b)

The rate constants for reactions (21a) and (21b) are 1.1×10^{-12} and 1.5×10^{-11} cm³/molecule s, respectively.^{258–260} This is the first major breakthrough in energy donor generator technology in the last 10 years.

1.5. Excited Halogen Atoms and Ozone Depletion

The role of Cl^{*} atoms in stratospheric chemistry is discussed by Tyndall *et al.*⁷⁹ It is assumed that at 30 km altitude the main source of Cl^{*} atoms is photodissociation of ClONO₂, and the main removal process is deactivation by O₂. It was concluded that the excited Cl^{*} atoms are unimportant in the stratosphere, since the rate of the photolytic production of the Cl^{*} atoms is small ($\leq 1\%$) in comparison with production of the Cl^{*} atoms in Cl+O₂ \rightarrow Cl^{*}+O₂ process.

Atomic bromine exhibits a 40 times more powerful atmospheric ozone depletion potential than a chlorine atom, in the stratosphere it depletes ozone via several chain reactions.²⁶¹ The contribution of excited Br* atoms in the depletion of ozone may easily be estimated from the data of the present review. Briefly, the main quencher of Br* atoms in the atmosphere must be CO₂ with a rate constant of 1.5 $\times 10^{-11}$ cm³/molecule·s; the key reactions of bromine atoms in atmosphere are Br+M (M=O₃, H₂CO, HO₂) with the rate constants of $\sim 10^{-11}$ cm³/molecule·s; since the concentration of CO₂ is several orders of magnitude larger than the concentrations of M molecules, the role of excited Br* is negligible.

The role of F* and I* atoms in the depletion of ozone is expected to be negligible also.

2. Excited Fluorine Atoms $F^{*}({}^{2}P_{1/2})$

Kinetics measurements on processes involving F* atoms are beset at least with two difficulties. One is the lack of simple and sensitive methods to detect F* atoms. The first resonant electronic transition occurs in the far vacuum ultraviolet (VUV) region at 95.5 nm, well below the LiF window cutoff at 106 nm. Therefore, one-photon excitation requires VUV generation and windowless conditions. Two-photon excitation seems even less promising because it requires large technical effort since the simultaneous absorption of two photons below 200 nm is necessary. The IR absorption lies near 400 cm⁻¹, this wavelength is available only for diode laser absorption spectroscopy. Another difficulty, arising in the case of photolytic production of F* atoms, is that only a few precursor molecules yield fluorine atoms from photolysis in the visible or UV spectral ranges. Hence the data on the chemistry of excited F* atoms are very limited.

2.1. Collisional Deactivation of F* Atoms

2.1.1. Molecular Beam Studies and Theoretical Predictions

In 1979, the interaction potentials for $F(^{2}P)$ + Ne,Ar,Kr,Xe systems were constructed from experimental differential cross sections for inelastic scattering obtained by Lee *et al.* in experiments with crossed molecular beams.^{262–264} In these measurements, very low collisional energy was achieved (0.02 eV for F+Xe and 0.036 eV for F+Ar). The authors employed the potentials to calculate inter and intramultiplet changing cross sections for F–Ar and F–Xe.²⁶⁴ These cross sections may be used to calculate the bimolecular deactivation rate constants at T=300 K, the "temperature of collision" *T* is estimated from the energy of collision *E* as $kT=\pi E/4$. The results are presented in Table 7.

Later, Aquilanti *et al.* continued the molecular beam studies of fluorine atoms.^{265,266} A magnetic beam technique with magnetic analysis of substates of fluorine atoms was used to measure absolute integral cross sections for scattering of fluorine atoms by Ar, Kr, and Xe. Using own experimental absolute integral cross sections, differential cross sections of Lee *et al.*, relative integral cross sections of Müller,²⁶⁷ and some spectroscopic data, Aquilanti *et al.* obtained new inter-

^cThe G-line of the EPR spectrum $(F, m_F: 0, 0 \leftrightarrow 1, -1)$ of F* atoms was used.

^dTheoretical predictions for $F^*+M \rightarrow F+M$ deactivation rate constant. The range of the values obtained for different potentials is presented. ^eMolecular beam study at very low collisional energy.²⁶⁴

^fOnly $F^* + Br_2 \rightarrow Br^* + BrF$, $F + Br_2 \rightarrow Br + BrF$ reactions for removal of fluorine atoms were assumed, the bromine atoms were detected by a Br laser.

action potentials for F–Ar, F–Kr, and F–Xe. Unfortunately, it is rather difficult to calculate the room temperature deactivation rate constants from these data.

Using interatomic potentials from molecular beam studies of Lee *et al.* and Aquilanti *et al.*, Reznikov and Umanskii have theoretically calculated the cross sections and the rate constants both for $F^* + M$ deactivation²⁶⁸ (see Table 7) and for EPR line broadening.²⁶⁹ There are large disagreements, about 1–2 orders of magnitude, between the rate constants calculated by Reznikov and Umanskii and by Lee *et al.*²⁶⁴ for collisional deactivation $F^* + Ar$, Xe at low collisional energies. Reznikov and Umanskii concluded that this disagreement is due to uncertainty in the experimental data on the interatomic potentials.

In closing the discussion of the theory of F^* + atom scattering we note, that close-coupled calculations for deactivation of F^* by protons H^+ have been done by Mies in 1973.^{270,271}

2.1.2. EPR Linewidth Studies

The cross sections of the broadening of the gas phase EPR linewidth of F^* atoms by different gases have been measured by Miller *et al.*^{272–274} and by Boltnev *et al.*¹⁵⁶ Using these cross sections, one may calculate the broadening rate con-

stants (see Table 7), which may be treated as the upper limits for the deactivation rate constants. Boltnev *et al.* concluded that in the case of F^* + He the contribution of the collisional depolarization of F^* atoms is small ($\leq 20\%$), and hence the measured rate constant for EPR linewidth broadening is close to the deactivation rate constant.

2.2. Reactions of F* with H₂ and HBr

2.2.1. Reaction F*+H₂

There is a discussion in literature on the relative reactivity of excited and unexcited fluorine atoms in the reaction with hydrogen

$$F+H_2 \rightarrow HF+H,$$
 (22a)

$$F^* + H_2 \rightarrow HF + H. \tag{22b}$$

There are three potential energy surfaces for these reactions, two of them (denoted $1^2A'$ and $1^2A''$ for collinear reaction) correlate to $F+H_2$, and one $(2^2A')$ to F^*+H_2 . The $2^2A'$ is strongly repulsive, and thus $F^* + H_2$ collisions must be completely nonreactive in the adiabatic limit. However, reaction (22b) may occur due to nonadiabatic crossing from the $2^2A'$ to the $1^2A'$ surface. In 1974, using classical-path calculations on diatomic-in-molecules surface, Tully demonstrated the importance of the nonadiabatic channel (22b) and predicted that $k_{22b} \approx 0.1 k_{22a}$.²⁷⁵ Since that time, a lot of theoretical predictions on the spin-orbital effects in the $F+H_2$ system have been done.^{276–310} Also, Baer and co-workers have published several theoretical papers on the reactions (22a), (22b) in a strong laser field.^{311–314} A top-level theoretical study was done by Alexander et al., who used a full ab initio calculation of the complete set of diabatic potential energy surfaces and spin-orbital terms for this system.²⁹⁹ The fitted surfaces and couplings have been used to perform exact time-dependent quantum scattering calculations of reaction transition probabilities. The main conclusion of this calculation is close to that of Tully, $k_{22b} \sim 0.04 k_{22a}$. One of possible the mechanisms for reaction (22b), clearly speculative but very popular, involves nonadiabatic electronic-rotational (E-R) energy exchange followed by reaction on the adiabatic $F+H_2$ surface in a single collision event

$$F^* + H_2(j=0) \rightarrow [F - H_2(j=2)] \rightarrow H + HF.$$
 (23)

Note that the efficiency of the first step, E-R exchange, was confirmed in many theoretical studies.

In large contrast with the large amount of theoretical studies, until quite recently there have been no experiments that have confirmed the presence of the nonadiabatic channel (22b). Moreover, in 1985 Lee and co-workers employed a high-resolution crossed molecular beam study, and no HF reaction product attributable to F* was detected neither in $F^* + H_2$,³¹⁵ nor in F* + D₂, HD³¹⁶ reactions. However, recently channel (22b) was finally observed in an experimental study of Nizkorodov *et al.*, who used infrared laser absorption to investigate the vibrational and rotational distribution of HF molecules in low-density crossed supersonic jets under single collision conditions.^{317,318} In these experiments, product states in the HF (v=3) manifold were observed that are energetically accessible only to channel (22b). This experimental study stimulated new theoretical studies^{299–304,306–310,319–322} in which it has been found that, except for very cold reactants, the F* state plays a minor role in determining the reactivity.

Recently Rusin *et al.* have studied reactions (22a), (22b) by measuring the high-resolution time-of-flight spectra of HF at collision energies E=69-81 meV.³²³ The results were compared with exact coupled-channel quantum mechanical calculations based on the Stark–Werner *ab initio* energy surface.³²⁴ Excellent agreement between the experimental and computed rotational distributions is found for the HF(v = 1,2), this fact confirms that the reaction dynamics for these product states is determined by pathway (22a) only. For HF ($v = 3, j \ge 2$), however, the agreement is less satisfactory, hence considerable contribution of pathway (22b) is assumed.

Note, however, that a new *ab initio* energy surface has been developed for the $F+H_2$ reaction just recently by Hayesa *et al.*³²⁵ Hayesa *et al.* carried out several preliminary scattering calculations using this new surface and predicted that the differential cross sections at low collision energy for the $F+H_2$ reaction may be drastically modified from the predictions based on the Stark–Werner surface.

2.2.2. Reactions of F* with HBr and DBr

Polanyi and co-workers carried out a crossed molecular beam study of the F*/F+HBr (DBr) reactions.⁹⁶ The ratio [F*]/[F] was varied by changing the temperature of the source. From the insensitivity of the product Br atom spinorbit distribution to the incident [F*]/[F] ratio, they concluded that, first, there is a substantial barrier to the adiabatic process F*+HBr \rightarrow HF+Br*, and, second, excited Br* atoms appeared due to the nonadiabatic process F+HBr \rightarrow HF+Br*. The conclusions on the reaction of F*/F with DBr are the same.

2.3. Production of F* Atoms by Photolysis

To the knowledge of the author there is only one measurement of F* quantum yields from photodissociation. In 1996 Zhang *et al.* have studied photodissociation of HF (v=3) in the VUV, where HF was vibrationally excited by a Ti:sapphire laser through an overtone transition, and H atoms were detected by the high-*n* Rydberg time-of-flight technique.⁶² From the time-of-flight profiles of H atoms the F* relative quantum yield was found to be 0.42 ± 0.02 and 0.41 ± 0.08 at 193.3 and 121.6 nm, respectively. The β parameter was determined to be -1.0 ± 0.05 at 193.3 nm photolysis for both ${}^{2}P_{1/2}$ and ${}^{2}P_{3/2}$ states of atomic fluorine; hence both channels derive from the perpendicular transition $A \, {}^{1}\Pi \leftarrow X \, {}^{1}\Sigma^{+}$.

In the adiabatic limit, when the atoms separate slowly, the relative yield of F^* atoms should be 0; in the diabatic limit when the atoms separate quickly, this yield should be 1/3; the experimental value is higher than both. The last theoretical

calculations of Brown and Balint–Kurti on the photodissociation of HF (v=0),³²⁶ HF (v=1,2,3) and DF $(v=1,2,3)^{327}$ agree well with the experimental results of Zhang *et al.* and predict a rather complicated dependence of the relative yield of F* atoms on the photon energy.

Also, the yields of F* atoms in the photolysis of WF₆ and UF₆ have been determined to be ≥ 0.4 and ~ 0.07 , respectively, in an indirect study of Gordon *et al.*⁹⁷ In this study, F*/F atoms were converted to Br*/Br atoms by the reactions F*/F+Br₂ \rightarrow Br*/Br+BrF, and the bromine atoms were detected by a Br laser. Note that this conversion mechanism has never been confirmed experimentally.

3. Excited Chlorine Atoms CI*(²P_{1/2})

3.1. Collisional Deactivation of CI* Atoms at *T*=300 K

The first studies on collisional deactivation of Cl* were reported by Husain *et al.*,^{69,328–331} who detected Cl* atoms by time-resolved atomic resonance absorption in the vacuum ultraviolet (ARA VUV). Later, the deactivation of Cl* atoms was studied by the time-resolved laser magnetic resonance (LMR) technique by Krasnoperov and Chichinin.^{54,55,159,206,332,333}

The rate of deactivation of Cl* by ICl was found to be 33 times lower than the rate of the $Cl+ICl \rightarrow I+Cl_2$ reaction,²⁰⁶ and this fact has stimulated the creation of a photodissociative-chemical laser, operating on the spinorbital transition of the chlorine atom.¹⁹⁹ This laser was applied by Sotnichenko et al. to study collisional quenching of Cl*, 75,208 and the results were in agreement with those obtained in LMR studies. At the same time, tunable diode laser absorption spectroscopy was originally applied to study Cl* quenching processes.^{72,334} Also, the rate constant for deactivation of Cl* by SO2 has been measured by Dolson and West by monitoring the infrared fluorescence from the fundamental SO₂ stretching levels.⁷⁸ Recently, Hitsuda et al. have used laser-induced fluorescence in the vacuum ultraviolet (LIF VUV) to detect Cl* and Cl atoms near 135 nm. LIF VUV and LMR methods are probably the best for studying Cl* deactivation processes, they have nearly equal sensitivity, about $[Cl^*] \sim 10^{10} \text{ cm}^{-3}$, but the time resolution of LIF VUV is better.

The rate constants for the collisional deactivation of Cl* at room temperature are listed in Table 8 in chronological order for each quencher.

3.1.1. First ARA VUV Measurements

The substantial disagreement (by orders of magnitude) between all ARA VUV data obtained in 1977–1984 by Husain *et al.*,^{69,328–331} and the data obtained by other methods is almost total. An agreement occurs only in four cases (Ne, CF_2Cl_2 , CF_4 , CCl_4); in three of them the rate constants are close to the gas-kinetic collision limit. The reasons for this disagreement have been discussed in several papers. The conclusion of the consideration is that these ARA VUV data cannot be recommended even as rough estimate. The probable sources of error in ARA VUV experiments have been outlined in Chichinin.¹⁵⁸ Some of these sources are:

(1) The VUV radiation used in these experiments photolyses many quenchers (for example, Cl_2 , O_2) and yields atoms other than Cl^* . The concentration of these atoms A is proportional to the concentration of the quencher Q, $[A] \sim [Q]$. From theoretical considerations it is known that the atoms A must deactivate Cl^* rather quickly. Hence the measured rate constant for deactivation of Cl^* may be overestimated due to contribution of the $Cl^*+A \rightarrow Cl+A$ quenching process.

(2) The rate constants k(M), where M=He,Ne,Ar,Kr,Xe, have been obtained from the $\tau^{-1} = \tau_0^{-1} + k(M)$ [M] dependencies, where τ is the first-order rate constant for the decay of the Cl* signal.³³⁵ The increase of τ^{-1} was very small, about 10%, and may be explained by other reasons except deactivation of Cl* by M. The only system in which the τ^{-1} increased strongly (~2 times) is the Cl* + Ne system, but in this particular case there is an agreement with the LMR data.

(3) In order to detect Cl^{*} atoms, Husain *et al.* used the absorption line $3p^4 4s({}^2P_{3/2}) \leftarrow 3p^5 ({}^2P_{1/2})$ near 136.34 nm. In the work of Clyne and Nip it was found that this line is not suitable to detect Cl^{*} atoms since at this wavelength there is also a strong absorption of ground state Cl(${}^2P_{3/2}$) atoms.⁶⁸

3.1.2. CI*+ICI, I₂

The rate constant for deactivation of Cl* reported by Park et al.³³⁴ is 1 order of magnitude higher than the constants obtained by Chichinin and Krasnoperov,²⁰⁶ Wang and Jones,⁷⁷ and by Boriev.⁸³ This discrepancy is in fact surprising since the rate constant for the similar process Cl* + NOCl reported by Park et al. is consistent with the value obtained by LMR method. The reason for the discrepancy is not clear, but it seems noteworthy that Park et al. overestimated several times the rather well established^{75,77,83,205,206} rate constant for the reaction $Cl+ICl\rightarrow I+Cl_2$. As it was proposed in Park *et al.*,³³³ the $7\% \pm 3\%$ admixture of I₂ in ICl in the work of Park et al. would explain both (Cl* + ICl and Cl+ICl) discrepancies between Park et al. 334 and the other authors, although it is not clear where such a large I₂ admixture in ICl should have come from. If this explanation is correct, one can estimate the rate constant for the $Cl^* + I_2$ deactivation process to be $(5.3 \pm 2.6) \times 10^{-11}$ $cm^3/molecule \cdot s.$

3.1.3. Deactivation of CI* Atoms by Hydrides

In contrast to the situation with excited I* and Br* atoms, from Table 8 it is apparent that deactivation of Cl* by H₂, D₂, HF, DF, HCl, DCl, and H₂O (and presumably CH₄) at T=300 K is predominantly due to *E-R*, *T* energy transfer since all *E-V* channels are endothermic; here *E*, *V*, *R*, and *T* denote electronic, vibrational, rotational, and translational energies. Note that the deactivation of Cl* via chemical reaction is unlikely, the deactivation proceeds mainly by physical quenching; this was proven in several cases (H₂, D₂, DCl, CH₄) in experiments in which the kinetics of ARA IR,

 $^{a}Cl^{*}+SO_{2}\rightarrow Cl+SO_{2}(\nu_{1}=1)/SO_{2}(\nu_{3}=1)$. The ν_{3}/ν_{1} population ratio was found to be 1.6±0.5, even through excitation of ν_{3} mode is 210 cm⁻¹ more endoergic than ν_{1} .⁷⁸

 $^b The reaction rate constant is <math display="inline">{<}10^{-11} \text{ cm}^3\!/\!\text{molecule}\!\cdot\!\text{s}^{.81}$

^cThe value is recalculated from experimental data,³³⁸ using the new rates of Cl*+Cl₂, CH₃F processes.^{54,82}

^dChemical reaction only.

LMR, and ARF VUV signals of Cl^{*} atoms have been compared for $Cl^* + hydrides$ and unreactive $Cl^* + CF_2Cl_2(CCl_4)$ systems.^{75,79,202} For $Cl^* + H_2$ system this conclusion was obtained from direct detection of H atoms.¹⁵⁵

Very small deactivation rates should be expected for Cl* + hydride systems, since the E-R energy exchange requires multiquantum rotational transitions in the hydrides. In reality, see Table 8, the rates of these processes are unexpectedly large, indicating a large probability for nonadiabatic E-Rtransitions, in strong contradiction with theoretical estimates.^{277,340} For example, Resnikov and Umanskii have carried out calculations for the $Cl^* + H_2$, D_2 quenching processes.³⁴⁰ The Landau-Zener formula with quadrupolequadrupole interaction as a perturbation was used. It was found that the main contribution comes from $Cl^* + H_2(J)$ $=4) \rightarrow Cl + H_2(J=6)$ and $Cl^* + D_2(J=5) \rightarrow Cl + D_2(J=7)$ transitions; the total rate constants for deactivation of Cl* by H_2 and D_2 are 5×10^{-13} and 7×10^{-15} cm³/molecule s, respectively, in strong disagreement with what is found experimentally.

3.1.4. The Reactions of CI* Atoms with Organic Compounds

Almost all existing kinetic data for quenching of $Cl^*({}^2P_{1/2})$ atoms do not distinguish between chemical reaction and physical quenching of the excited atoms. The only exception are the LIF VUV studies of Matsumi et al., in which the ratios $k_R/(k_O+k_R)$ have been determined for the reactions of Cl* with CH₄, CH₂D₂, CD₄, C₂H₆, C₃H₈, C_3D_8 , $n-C_4H_{10}$, and $i-C_4H_{10}$, respectively. ^{81,82,339} Here, k_R and k_0 are the rate constants for chemical reaction and physical quenching. The ratios have been determined to be $<0.1, <0.3, <0.3, <0.08, 0.26 \pm 0.07, <0.05, 0.31 \pm 0.08,$ and 0.22 ± 0.07 , respectively. The rate constants for reactions of Cl* with C₃H₈, n-C₄H₁₀, and i-C₄H₁₀ are \sim 30% of those for ground state Cl atoms. This observation suggests that the reactions of Cl* and Cl with alkanes RH proceed via different mechanisms. The reactant state Cl+RH adiabatically correlates to the product ground state $HCl(^{1}\Sigma^{+}) + R$, while $Cl^* + RH$ correlates to a highly excited product state. Hence the reaction Cl*+RH should occur via non-adiabatic coupling between the two surfaces.³³⁹

3.1.5. Theoretical Predictions for the Deactivation Processes

To date there exist theoretical studies for the deactivation processes of Cl* atoms by rare gases,^{268,341–343} by H₂, D₂, and HD,^{277,340,344,345} and by HCl.^{346–351} For illustrative purpose, in Table 9 we present a brief summary of theoretical predictions for deactivation at T=300 K. As for the Cl* + He,Ne,Ar,Kr,Xe series, the predictions are in excellent agreement with experiment for Cl* + He, in all other cases both experimental and theoretical data have too large uncertainties, see Table 8. The theoretical estimates for Cl* + H₂,D₂ are far from experimental results; however, the estimates illustrate, the *E*-*R* near-resonant energy exchange is much more efficient for Cl* + H₂ that for Cl* + D₂, in contradiction with experiment.

TABLE 9. Theoretical predictions for the Cl*+M deactivation rate constants at T= 300 K

^cAIP=*ab* initio potential is used.

^dNT, ERT=a simple Landau–Zener curve crossing description, nonadiabatic transitions between electrorotational terms are assumed.

3.2. High-Energy Reactions and Deactivation of CI* Atoms

3.2.1. Early Studies on CI* Atom Scattering

In 1979, Lee and co-workers used a molecular beam technique to obtain the interaction potential for Cl–Xe.^{264,355} In these works the parameters of the potential were clarified and a cross section $\sigma(1/2 \rightarrow 3/2) = 7.8 \times 10^{-5} \text{ Å}^2$ at collisional energy of 0.00282 eV was calculated. Note that this collisional energy corresponds to the temperature T= 26 K. Later, Aquilanti *et al.* continued molecular beam studies of Cl* atoms, and the parameters for the three lowest potential energy surfaces and the nonadiabatic coupling matrix for Cl*/Cl+He, Ne, Ar, Kr, Xe, H₂, D₂, and CH₄ systems were obtained.³⁵⁴

3.2.2. The Reaction of CI* Atoms with CH₄

In reactions of halogen atoms, the ground spin-orbit state ${}^{2}P_{3/2}$ is generally considered to be more reactive than the excited ${}^{2}P_{1/2}$ state due to the adiabatic nature of the corresponding potential surfaces.⁵ A laser flash photolysis-resonance fluorescence kinetics study of the reaction $Cl({}^{2}P) + CH_{4} \rightarrow CH_{3} + HCl$ was studied by Ravishankara and Wine at T = 221 - 375 K.³⁵⁶ The low temperature result obtained in this investigation, the non-Arrhenius behavior of the rate constant, and all previous investigations can be rationalized in terms of a model which assumes that the $Cl^{*}({}^{2}P_{1/2})$ state reacts with CH_{4} much faster than the $Cl({}^{2}P_{3/2})$ state.³⁵⁶

The indirect comparison of Cl^{*} and Cl reactivity with CH₄ near the reaction threshold (collision energy of 0.13-0.16 eV) have been done recently by Kim *et al.*¹⁸² In this study Cl^{*} atoms were produced by photodissociation of BrCl at 420 nm and CH₃ product spatial anisotropy was studied by

REMPI (2+1); that is, PHOTOLOC (photoinitiated bimolecular reaction by low-of-cosines) technique was used. Kim *et al.* cannot claim that the $Cl^* + CH_4$ channel is less reactive than $Cl+CH_4$, but they can rule out the possibility of the role of Cl^* reactivity in the explanation of the non-Arrhenius behavior at low temperatures.

3.2.3. The Reaction of CI* Atoms with H₂

Until 1999, the reaction of Cl atoms with H₂ was assumed to proceed via adiabatic the ground state surface only, $Cl({}^{2}P_{3/2}) + H_{2} \rightarrow H + HCl$, and the upper $Cl^{*}({}^{2}P_{1/2})$ state was assumed to be nonreactive.³⁵⁷ However, "a rule is done to be broken;" recently, Lee *et al.* have studied the reactions

$$Cl^*/Cl + H_2 \rightarrow HCl + H,$$
 (24a)

$$Cl^*/Cl + D_2 \rightarrow DCl + D,$$
 (24b)

 $Cl^*/Cl + HD \rightarrow DCl + H,$ (24c)

$$Cl+HD \rightarrow HCl+D,$$
 (24d)

with a rotating-source, crossed-beam technique. Two different sources for generating the Cl(²P) beam were used, the concentrations of the two reactants (Cl* and Cl) and the H and D atom product were monitored by REMPI (1+1').^{85,344,358} Lee *et al.* reported that in reaction (24a) the excited Cl* atom is two times more reactive to H₂ than the ground state Cl reactant in the range of collisional energies from threshold near 3.8 kcal/mol till 9 kcal/mol: $\sigma^*/\sigma \approx 2$, here σ^* and σ denote reaction cross sections for Cl^{*} and Cl atoms, respectively. For reactions (24b) and (24c) the relative reactivity of Cl* is lower than that of Cl atoms at small collisional energies and higher at large collisional energies; for reaction (24d) the ground state Cl atom is always more reactive than the excited Cl* atom.⁸⁵ Lee et al. have also pointed out that in the ion-molecular reaction $Ar^+({}^2P_{1/2})$ $+H_2 \rightarrow ArH^+ + H$ studied by Tanaka *et al.*^{359,360} the spinorbitally excited $Ar^+({}^2P_{1/2})$ ion is more reactive than the ground state $Ar^+(^2P_{3/2})$ ion by a factor of ~1.4.

However, the recent molecular beam study of Balucani *et al.*³⁶¹ put the results of Lee *et al.* in some doubt. In this study a combined experimental and theoretical determination of the differential cross sections of the Cl*/Cl+H₂ reaction was done q1 at 3.85, 4.25, and 5.85 kcal/mol collisional energies. Balucani *et al.* have found that the Cl* atom is much less reactive than it was reported by Lee *et al.*; the product rotational distributions were also different. However, the direct comparison between the results of Balucani *et al.* and Lee *et al.* is not possible, because of the differences in the initial H₂ rotational distributions and in the collisional energies.

In addition, one should note the last calculations^{362–364} on $Cl^* + H_2$ system based on the potential surface of Alexander *et al.*³⁶² The results of these calculations disagree with the measurements of Lee *et al.*^{344,358} and Dong *et al.*,⁸⁵ the relative reactivity of Cl* was found to be lower than that of Cl atoms.

Recently, the scattering in $Cl^* + D_2$, He systems was studied by Parsons and Chandler by means of crossed-molecularbeam techniques with velocity-mapped ion imaging.³⁶⁵ These experiments were done at collision energies *E* above and below the energy of the reaction barrier (4.9 kcal/mol). The upper limit for the cross section for electronically nonadiabatic quenching

$$Cl^* + D_2(j=0) \rightarrow Cl + D_2$$
 (25)

was determined to be $\sigma \le 15^{+44}_{-15} \text{ Å}^2$ at E = 7.6 kcal/mol, the probability of process [Eq. (25)] was found to be indistinguishable to that for the kinematically identical system of Cl*+He.

3.3. Production of CI* Atoms by Photolysis

The data for Cl^{*} relative quantum yields and β parameters are presented in Table 10 in chronological order for each parent molecule M.

3.3.1. Photodissociation of HCI and DCI

In recent years, the yield of Cl* atoms in the photodissociation of HCl was studied in a number of experimental (see Table 10) and theoretical works.^{369,426-430} Its first UV absorption bands correspond to the singlet electronically excited state $A^{1}\Pi$ and to several triplet states. The $A^{1}\Pi$ and three other triplet excited electronic surfaces $(a^{3}\Pi_{2}, a^{3}\Pi_{1})$ and $a^{3}\Pi_{0^{-}}$) correlate adiabatically with H+Cl while the $a^{3}\Pi_{0^{+}}$ and $t^3 \Sigma_1^+$ surfaces correlate with H+Cl*.^{175,189,190,193} The spin-orbit interaction in the chlorine atom is rather small (in comparison with iodine and bromine atoms) and therefore the photoexcitation is restricted primarily to spin-conserving transitions, i.e., the perpendicular transition $A^{1}\Pi \leftarrow X^{1}\Sigma^{+}$ is much more important than those to triplet states. Hence the yield of Cl* atoms in photodissociation through photoexcitation of $a^{3}\Pi_{0^{+}}$ and $t^{3}\Sigma_{1}^{+}$ states must be very small, and the β parameter is close to -1.

In reality, the yields of Cl* atoms in photodissociation of HCl (and DCl) at 143-235 nm are close to the statistical limit of 1/3 (see Table 10), indicating strong nonadiabatic coupling between the $t^3 \Sigma_1^+$ and $A^{-1}\Pi$ excited surfaces at large H-Cl distances. Quantitative agreement has been reported between experimental studies of Lambert et al.¹⁷⁹ and a high-level, time-independent quantum dynamics computation involving ab initio electronic states and coupling terms of Alexander et al.⁴²⁷ Recently, Regan et al. have studied the photodissociation of HCl in selected rovibrational states (v = 1-3) at 235 nm.³⁶⁹ The branching Cl*/Cl ratio measured with the REMPI technique have been compared with theoretical predictions. The experimental results and the predictions share a common qualitative trend, although quantitative agreement occurs only for HCl(v=2). New refined *ab initio* calculations of HCl potentials have recently been published⁴³¹ and might improve this agreement. It is interesting, that Gilvertz and Balint-Kurti have predicted that Cl*/Cl

^aThe photolysis wavelength λ (or the range for λ) and yield of Cl* (or the range for the yields) are presented. The relative yields for ³⁵Cl* and ³⁷Cl* isotopes are presented as Γ_{35}/Γ_{37} . $\Gamma \sim 0$ means "below the detection limit."

^bThe wrong values for Cl*/Cl ratios measured by Matsumi et al.^{189–191} have been corrected later.¹⁹³

^oThe yields of Cl* are 40.8±3.3, 40.4±2.4, 47.5±1.9, 40.8±2.8, 44.4±2.1, 41.3±2.3, 34.5±2.9, and 33.4±4.8% for 193.3, 205.5, 209, 214, 220, 225, 230.4, and 235.3 nm, respectively.

^dThe yields of Cl* are 42.3, 44.3, 45.2, 48.4, and 44.1% (±7%) for 201, 203, 205.5, 208.2, 210 nm, respectively.

^eLIF VUV: tripling technique, CO is used for tripling of 405 nm photons.

^fThe yields of Cl* are 51 ± 5 , 53 ± 6 , 44 ± 7 , 43 ± 6 , 40 ± 6 and $41\pm 7\%$ for (v,J)=(1,0), (1,5), (2,0), (2,11), (3,0), and (3,7) rovibrational states of HCl.

^gLIF VUV: four-wave mixing $(2\omega_1 - \omega_2, \omega_1 = 212.56 \text{ nm}, \omega_2 \sim 500 \text{ nm})$ technique: compared to the tripling technique, it is much more intensive and stable. ^bThe yields of Cl* are 28±5, 29±12, 22±8, 30±6, and 28±8% for 200, 205.5, 210, 215, and 220 nm, respectively.

ⁱThe yields of Cl* are 0.94 ± 0.2 , 1.57 ± 0.1 , 4.1 ± 0.3 , 5.0 ± 0.3 , 8.3 ± 0.5 , 12.5 ± 0.5 , 14.9 ± 1.3 , 20 ± 2 , 21.9 ± 2.5 , 22.5 ± 1.2 , 27.0 ± 1.1 , 23.7 ± 2.4 , 30.1 ± 1 , 31.0 ± 1 , 32.0 ± 2.4 , 28.6 ± 1 , $20.6\pm1.3\%$ for 308, 355, 375, 380, 385, 390, 395, 400, 405, 450, 455, 460, 465, 470, 475, 480, and 485 nm, respectively. The β parameters are -0.7 ± 0.2 , 1.8 ± 0.2 , 2.0 ± 0.2 , and 2.0 ± 0.2 for 308, 355, 370, and 400 nm, respectively.

^jThe yields of Cl^{*} are 0.30, 0.60, 1.00, 1.96, 4.58, 5.30, 8.34, 10.31, 17.56, 21.94, 30.02, 40.62, 42.03, 42.99, 41.38, 40.30, 40.83, and 40.65% for 350, 355, 360, 365, 370, 375, 380, 385, 390, 395, 400, 420, 430, 440, 450, 460, 465, and 470 nm, respectively. The β parameters are 2±0.08, 1.73, 1.68, 1.58, 1.54,

1.15, 0.84, 0.24, -0.06, -0.33, -0.47, and -0.64 for >370, 360, 355, 350, 345, 340, 335, 330, 325, 320, 315, and 310 nm, respectively. There is a contradiction: in the text it is mentioned that $\beta = -0.9$ at 310 nm.

^kThe yields of Cl* are 51.0, 60.0, 62.0, 50.0, 25.9, and 11% for 500, 480, 450, 420, 400, and 390 nm, respectively.

 ${}^{1}\beta \sim -1$ and $\beta = 1.0-1.6$ for the 235–262 nm and 400–540 nm wavelength ranges, respectively. In the 320–410 nm range the yield of Cl* is close to zero. ^mThe yields of Cl* are 30.4, 38.5, 40.7, 50.6, 51.6, 53.6, 58.6, 62.0, 63.3, 66.9, 66.4, 67.1, 68.6, 66.8, 64.9, 60.6, 50.7, and 38.7% for 526, 518, 510, 502, 497, 495, 488, 481, 474, 467, 461, 455, 448, 442, 437, 431, 425, and 420 nm, respectively, in the photodissociation of BrCl(v = 0); 43.5, 54.2, 61.8, 68.4, 71.7, 74.6, 74.9, 75.5, 81.7, 82.0, 74.4, 42.4, 15.6, 8.9, 7.6, 10.2, 15.1, 1.1, and 8.5% for 534, 526, 518, 510, 502, 497, 495, 488, 481, 474, 467, 461, 455, 448, 442, 437, 431, 425, and 420 nm, respectively, in the photodissociation of BrCl(v = 1); 68.6, 63.1, 84.9, 71.5, 70.4, 60.0, and 37.8% for 551, 542, 534, 526, 518, 510, and 502 nm, respectively, in the photodissociation of BrCl(v = 2).

ⁿThe yields of Cl^{*} are 51.5, 40.8, 37.0, 33.3, 26.6, and 25.0% for 530, 520, 510, 500, 490, and 480 nm, respectively. These Γ values presents the yield of Cl^{*} from the photodissociation of ICl(B³ Π_{0+}) state only due to parallel transition.

^oThe yields of Cl* are 41, 58, 66, 73, 75, 76, 78, 79, 77, 76, 77, 76, 75, 73, 71, and 58% for 437, 450, 455, 460, 465, 470, 475, 480, 485, 490, 495, 500, 505, 510, 520, 532 nm, respectively.

 $p_s*/s = 0.20 \pm 0.04$ is the ratio of REMPI signals of Cl* and Cl atoms at 237.808 and 236.286 nm, respectively.

 q Rogers *et al.* have concluded from analysis of angular and velocity distributions of chlorine atoms that I*+Cl and Cl*+I channels dominate over I+Cl and I*+Cl*.

^rThe β parameter is measured for each of the two channels: ICl \rightarrow I^{*}+Cl^{*}/Cl, 30%, β =1.7 and ICl \rightarrow I+Cl^{*}/Cl, 70%, β =-0.5.

^sThis previous value is incorrect.

 $^t\!The$ yields of Cl* are <2, <2, 14±2, and 45±4% for 600, 562, 478, and 355 nm, respectively.

^uThe speed distribution of Cl^{*} atoms and the speed dependence of the β parameter are obtained.

^vThe quantum yield of chlorine atoms (both Cl and Cl*) is determined.

^wThe signals of Cl^{*} and Cl atoms were of the same order of magnitude.

The speed distributions of Cl atoms contains 3 peaks, at 2540, 1810, and 1075 m/s; $\beta = 0.68$, 0.10, and 0.00–0.10, respectively.

^yVibrational energy of CH₃Cl^{*} is \approx 13800 cm⁻¹.

^zVibrationally mediated photodissociation: the C-H stretch overtone level in the vibrationally excited molecule is shown.

^AThe overall [i.e., Cl^*+Cl] quantum yield for chlorine atoms is 0.72,⁷⁹ 0.8 ± 0.20 ,⁴⁰⁹ and 0.42 ± 0.1 .¹⁶¹ See also references in the paper of Tyndall *et al.*⁴⁰⁹ ^BThe yields of Cl* in the photodissociation of excited CHFCl₂ in 3₁, 7/2₂, and 4₁ vibrational states (vibrational energies are 8708, 9905, and 11387 cm⁻¹) are 34.2, 32.4, and 32.9%, respectively.

 $^{C}\beta = 0.36 \pm 0.06, 0.43 \pm 0.05, \text{ and } 0.34 \pm 0.04$ for the photodissociation of excited CHFCl₂ in 3₁, 4₁, and 5₁ vibrational states.

DRelative values, reference comparison process is photodissociation of HCl.

^EThe probabilities of CF₂Cl+Br and CF₂Br+Cl channels are 0.96 and 0.04, respectively.

^FPhotolysis of C₂H₃Cl at 193 and 210 nm: $\beta_{193} = 0.30 \pm 0.02$ and $\beta_{210} = 0.32 \pm 0.2$ for low-speed Cl* atoms, $\beta_{193} = 1.09 \pm 0.2$ and $\beta_{210} = 0.96 \pm 0.2$ for high-speed Cl* atoms.

^GDifferent velocity distributions for Cl* and Cl are assumed. The assumption is based on photofragment spectroscopy results.^{424,425}

branching ratio depends quasiperiodically on vibrational energy of excited HCl molecule.⁴²⁶ Another theoretical prediction on the effect of parent vibration on the Cl*/Cl branching ratio is presented by Gersonde *et al.*⁴²⁸

3.3.2. Isotope Effect in the Photodissociation of Chlorides

In 1994, Deshmukh and Hess used REMPI techniques and observed very large and ununderstandable isotope effects in the photodissociation of CCl_4 , $CHCl_3$, and Cl_2 .¹⁶² Recently, the result was checked by Maul *et al.*⁴¹³ for CCl_4 , and the isotope effect was not observed at all, $[^{35}Cl^*]/([^{37}Cl^*] = [^{35}Cl]/([^{37}Cl] = 3$. This fact put in doubt the existence of the large isotope effects and hence all these data of Deshmukh and Hess.

3.3.3. Velocity Distributions of CI* in Three-Body Decay

The photoion imaging technique⁴³² yields a great deal of information on the photodissociation dynamics; recently, the technique was used to study the photodissociation of several chlorides ($COCl_2$,⁴⁰⁰ S₂Cl₂,⁴⁰⁴ SOCl₂⁴⁰³) where three-body decay is possible. The analysis of the velocity (speed and angle) distributions of Cl* and Cl photofragments gave a deeper insight into the dynamics of the photodissociation: it includes not only information on the excited states which participate in the process, but also on the mechanism of three-body decay, which may be, in principle, sequential, synchronously concerted and asynchronously concerted.^{398,399} Note that the velocity distributions for Cl* and Cl photofragments may be very different, as it was observed for $COCl_2$ and $CSCl_2$.

3.3.4. Vibrationally Mediated Photodissociation of Chlorides

The effect of vibrational excitation of polyatomic chlorides on the Cl*/Cl branching ratio in the photolysis of these chlorides was studied by groups of Dagdigian *et al.* and Rosenwaks *et al.* Lambert and Dagdigian have shown that the vibrational excitation in the fourth C–H stretch overtone in CH₃Cl greatly increases the Cl*/Cl branching ratio in the photolysis near 238 nm, from 0.27 for unexcited to 1.08 for an excited molecule.³⁶⁷ The reason for this effect is unclear. There was no detectable dependence of the Cl*/Cl ratio upon rotational excitation of CH₃Cl.³⁶⁷ The degree of enhancement of the signals of H atoms was much less than that for Cl atoms.⁴³³

Later, the Cl*/Cl branching ratio was determined in the photodissociation of vibrationally excited CH₃Cl,^{367,406,433} CHD₂Cl,⁴⁰⁵ CH₃CFCl₂,⁴¹⁸ CHFCl₂,^{410,411} and CH₂Cl₂⁴⁰⁷ (see Table 10). All these determinations may be summarized as follows: the Cl*/Cl ratio increases with vibrational excitation, going to the statistical ratio [Cl*]/[Cl]=1/2 for all these chlorides, except CH₃Cl, where this ratio is higher.

Note that the Cl*/Cl branching ratio measured in photo-

dissociation of hydrogen-containing chlorides is often less informative on the nature of the upper electronic state of the transition, in comparison with photodissociation of iodides, since almost normally the ratio is dictated by nonadiabatic dynamics as the photofragments separate and not in the initial excitation.^{179,367}

3.3.5. Kinetic Energy Distribution Determination by Infrared Absorption Methods

The average kinetic energy of halogen atoms may be determined from the Doppler width of the absorption lines of the ${}^{2}P_{1/2}$ - ${}^{2}P_{3/2}$ transition by IR absorption methods. It is useful to notice that this method may produce a very large error, if the velocity distributions of X and X* atoms are different.

For example, the average kinetic energy of chlorine atoms produced by the photolysis of S_2Cl_2 was determined by Park *et al.* from the IR spectral widths to be 7 ± 1 and 10 ± 3 kcal/mol at 248 and 193 nm, respectively.³³⁴ Using a three-dimensional variant of the ion imaging method, Einfeld *et al.* have determined that the average kinetic energy of the chlorine atoms produced by the photolysis of S_2Cl_2 at 235 nm is much larger, 24 and 13 kcal/mol, for Cl* and Cl, respectively.⁴⁰⁴ This disagreement may be explained by the speed distributions of the atoms: excited Cl* atoms are much faster than the ground state Cl atoms.⁴⁰⁴ As a result, the IR absorption on Cl*-Cl transition is saturated for fast atoms and hence only slow atoms contribute to the width of the IR spectral lines.

3.3.6. MOCI→MO(²Π_Ω)+CI*/CI (M=N,H): Correlation of Spin-Orbit States of Products

Cao *et al.*³⁹¹ have demonstrated that the absorption band of NOCl consists of five bands; A and B bands correlate to $Cl^* + NO$ and $Cl + NO^*$, C and D bands correlate to Cl+ NO, and the band E correlates to $Cl + NO^*$; here NO and NO* denote ground state ${}^2\Pi_{1/2}$ and excited ${}^2\Pi_{3/2}$ spinorbital states of NO. These correlations have been observed experimentally and explained with the correlation diagram analysis.

Offer and Balint-Kurti have predicted theoretically that in the photodissociation of HOCl at the peak of absorption maximum (244 nm), first, the Cl*/Cl branching ratio is 0.45 for OH(${}^{2}\Pi_{3/2}$) channel and 0.59 for OH(${}^{2}\Pi_{1/2}$) channel; second, there is a strong variation of the Cl*/Cl ratio with the rotational number *j* of OH.⁴³⁴

3.3.7. Aligned Molecules: Effect on the Yield of CI* Atoms

A strong nonresonant laser field may be used to align the molecules due to the interaction of the induced dipole moment of the molecule with the electric field of the laser radiation. The alignment may be studied by measurement of the velocity anisotropy of the photofragments obtained in the photodissociation of the aligned molecules.

In experiments of Sugita *et al.*³⁷⁹ nonresonant Nd:YAG radiation (1.06 μ m) was used to align Cl₂ molecules and the

degree of alignment was determined from the velocity anisotropy of the $Cl(^{2}P_{3/2})$ atoms obtained from the photodissociation of Cl_{2} molecules at 404.17 nm,

$$Cl_{2}(X^{1}\Sigma_{g}, \Omega=0) + h\nu \rightarrow Cl_{2}(B^{3}\Pi_{u}^{+}, \Omega=0) \rightarrow Cl + Cl^{*}$$

$$(26a)$$

$$\rightarrow Cl_{2}(^{1}\Pi_{u}, \Omega=1) \rightarrow Cl + Cl.$$

(26b) The branching ratio without alignment is $\Phi_{\parallel}/\Phi_{\perp}$ = 2.0±0.1, where Φ_{\parallel} and Φ_{\perp} are quantum yields of channels (26a) and (26b), respectively. The β parameter for chan-

the Nd:YAG laser. Note that the yield of Cl* atoms in the UV photodissociation of Cl₂ was recently studied theoretically by Buenker *et al.*⁴³⁵ In this *ab initio* configuration interaction study, potential energy curves for the $X^{1}\Sigma_{g}^{+}$ ground state and $\Omega = 0_{u}^{+}$, 1_{u} valence states and dipole moments for transitions between these states were determined. The calculated yield of Cl* atoms as a function of excitation wavelength was shown to be in good agreement with experimental results of Samartzis *et al.*¹⁶³

nel (26a) was found to be 1.4. It was demonstrated that the

ratio $\Phi_{\parallel}/\Phi_{\perp}$ increases by a factor of 1.5 with the power of

3.4. Production of CI* Atoms in Chemical Reactions

3.4.1. Reactions of I* Atoms with Cl₂ and ICI

Since the production of X* atoms in chemical reactions has been reviewed by Dagdigian,⁵ here we discuss only some processes. The data for Cl* relative quantum yields from chemical reactions are presented in Table 11, in all cases the Cl* atoms were detected by direct methods. As one can see from Table 11, the reaction of I* with ICl is a new good example of $Y*+XZ\rightarrow X*+YZ$ (X, Y, and Z are halogen atoms) electronic-excitation-transfer reaction.

There is some doubt concerning the deactivation of I^* by Cl_2 ,

$$I^* + Cl_2 \rightarrow Cl^* + ICI, \qquad (27a)$$

$$\rightarrow$$
 Cl+ICl, (27b)

$$\rightarrow$$
I+Cl₂. (27c)

According to Lilenfeld *et al.*, the fraction of channel (27b) is about 1/3, and the main channel is (27c); that is, $k_{27b} = (5.5 \pm 0.8) \times 10^{-15}$, $k_{27a} + k_{27b} + k_{27c} = (1.7 \pm 0.7) \times 10^{-14}$ cm³/molecule s, and $k_{27b} > k_{27a}$.⁵⁶ However, Lilenfeld *et al.* wrote: "...the rate constant k_{27b} is the largest of the reactive rate constants [although Cl*(²P_{1/2}) could be formed and deactivated to Cl(²P_{3/2}) before detection under these flow conditions]." Hence, no strict conclusions may be drawn in this situation on the yield of Cl* atoms in the I*+Cl₂ process.

3.4.2. *R-E* Energy Exchange: Nonadiabatic Transitions in the Exit Channel

Let us discuss the reactions $A+HCl\rightarrow Cl^*/Cl+AH$, where A is an atom. The correlation diagrams for $A = O(^{1}D)$ and F are presented in studies^{439,442} and studies, 5,87,443 respectively; for A=H the diagram is given in many papers devoted to F+H₂ and Cl+H₂ reactions. In all these cases the reaction proceeds via the ground potential energy surface which correlates with ground state Cl atoms as products of the reactions. The exception is the reaction $O(^{1}D)$ + HCl, but the available excited state $^{1}A''$ of HOCl molecule also correlates with $OH+Cl(^{2}P_{3/2})$. Thus, in the adiabatic limit the [Cl*]/[Cl] branching ratio must be zero; hence, the production of the X* atoms is due to nonadiabatic transitions. These transitions must take place in the exit channel region at large distances between the products of the reaction, where the energy difference between the surfaces correlating to Cl and Cl* is minimal.⁴³⁹ It is interesting to note that this large-distance interaction is rather efficient in the case of interaction of chlorine atoms with several hydrides.

As discussed above, it is established that many $Cl^* + HA$ deactivation processes (HA=HF, DF, HCl, DCl, H₂O,...) occur via rather quick electronic-rotational *E*-*R* energy transfer. It is tempting to propose that an efficient *E*-*R* energy exchange for Cl* atoms plays the same key role as *E*-*V* energy exchange for Br* and I* atoms; that is, not only these deactivation processes but also the production of Cl* atoms in several chemical reactions $[O(^1D) + HCl,F+HCl,...]$ and from several photodissociation processes (HOCl+*hv*,...) occur via nonadiabatic *E*-*R* energy exchange.

Thus, the yields of Cl* atoms in the O(¹D)+HCl(DCl) reactions via E-R energy exchange OH(j)+Cl \rightarrow OH(j')+Cl \approx due to long-range dipole–quadrupole interaction between OH(OD) and Cl were estimated.⁴⁴² These yields were found to be in agreement with experimental results for the O(¹D)+HCl reaction, but a significant disagreement was found for the O(¹D)+DCl reaction.

4. Excited Bromine Atoms Br*(²P_{1/2})

4.1. Collisional Deactivation of Br* Atoms at *T*=300 K

The data for the collisional deactivation of Br* at room temperature are presented in Table 12. From the table it can be seen that the studies of collisional deactivation of Br* may be divided into three groups. The first is a broad study from 1970 by Donovan and Husain by means of flash photolysis-atomic resonance absorption in the vacuum ultraviolet (ARA VUV).^{1–3,86,444,445} The second group is made before 1980 and consists of numerous studies of different authors who mainly used detection of spontaneous infrared emission from Br* atoms (SE IR); the third group is the study of Johnson, Perram, and Roh in 1996.⁴⁴⁶ The results of the first group usually are unreliable and in strong disagreement with all later measurements.

4.1.1. The Study of Johnson, Perram, and Roh

Most of the recent data on collisional deactivation of Br^{*} was obtained in the study of Johnson, Perram, and Roh.⁴⁴⁶ In the study, pulsed lifetime measurements yielded absolute rate constants for the Br^{*} + Br₂ and Br^{*} + CO₂ deactivation processes, and the rates for many other gases relative to that for Br₂ ($k_{Br_2} = 1.24 \times 10^{-12} \text{ cm}^3/\text{molecule} \cdot \text{s}$), were determined in steady-state photolysis experiments.

Note also that, according to Johnson *et al.*, the lowest quenching rate constants (Br*+He, Ne, Ar, Kr, Xe, O₂) should be regarded as upper bounds to the true value. One can estimate that the measured lowest values may be explained either by impurities in the buffer gases, by trimolecular relaxation Br*+Br+M \rightarrow Br₂+M, or by bimolecular relaxation Br*+Br \rightarrow 2 Br; these estimates are based on the rather short experimentally observed lifetime of Br* and on the rather large degree of decomposition of Br₂. Note that such a situation is not rare; for example, the rate

constant for $I^* + Cl_2$ deactivation was overestimated by several authors because of neglecting the contribution from the $I^* + Cl \rightarrow I + Cl$ quenching process.²⁰³

4.1.2. Br*+H₂ Studies

Nesbitt and Leone have carefully studied the quenching of Br^* atoms by H_2 .⁴⁴⁷ It was found that this process must be studied in the absence of complicating effects which can arise from the previously unreported equilibrium process

$$Br^* + H_2(v=0) \rightleftharpoons Br + H_2(v=1).$$
 (28)

Nesbitt and Leone inspected the experimental conditions in the previously reported studies^{88,445,448} of this process and concluded that this equilibrium is probably responsible for the large discrepancies in these early measurements.

Truhlar *et al.* have confirmed by converged quantum reactive scattering calculations that the deactivation of Br* by H₂ proceeds mainly via the near-resonant E-V energy transfer (28).⁴⁴⁹⁻⁴⁵¹ The same conclusion was obtained by Miller *et al.*^{452,453} Later, using a (2×2) diabatic model originally developed by Truhlar and co-workers, Takayanagi and Kurosaki have found that the contribution of the chemical reaction Br* + H₂ \rightarrow HBr+H is small.⁴⁵⁴

Nesbitt and Leone also concluded, that $Br^* + H_2(v=1)$ is efficiently quenched to $Br + H_2(v=2)$ in the entrance channel, followed by a subsequent H atom abstraction from vibrationally excited H_2 :

Ab initio calculations for the $Br \cdots H_2$ prereactive complex have been published recently by Klos *et al.*⁴⁵⁵

4.1.3. Selective Spin-Orbit Effect: Reactions of Br* with IBr

The relative reactivity of Br* and Br atoms in collisions with IBr,

$$Br + IBr \rightarrow I + Br_2, \qquad (30)$$

$$Br^* + IBr \rightarrow I + Br_2, Br + IBr,$$
 (31)

was first correctly established by Clyne and Cruse⁴⁵⁶ and by Haugen *et al.*⁴⁵⁷ The ground state reaction (30) ($k_{30} = 4.6 \times 10^{-11}$,⁴⁵⁷ 3.5×10^{-11} cm³/molecule s²⁰⁵) proceeds at a rate ≥ 18 times faster than the rate of the total Br* deactivation, $k_{31} = 1.9 \times 10^{-12}$ cm³/molecule s. This fact is important for the development of a Br*-Br laser based on the photolysis of IBr, since the selective ground state depletion significantly enhances the laser gain.

4.1.4. E-V Energy Transfer

It is well established that deactivation of Br^* and I^* atoms by polyatomic molecules usually occurs via electronic to vibrational E-V energy transfer. Originally such processes were discussed in terms of two possible mechanisms: nearresonance long-range multipolar interactions and nonadiabatic curve crossings (see discussion in Sec. 6.2). The temperature dependence of the deactivation rate constants must be negative in the first case and may be different in the second. In experiments of Reisler and Wittig^{458,459} a negative temperature dependence for the Br*+CO₂ deactivation was measured; thus, a dominance of the near-resonance longrange multipolar interaction mechanism is possible. In the case of Br*+HCl the rate constant is nearly independent of temperature, and the energy defect for *E*-*V* energy transfer is large (789 cm⁻¹).^{458,459} Hence the curve-crossing mechanism is likely to be responsible for the deactivation of Br* by HCl.

4.2. Production of Br* Atoms by Photolysis

The data for Br* relative quantum yields and β parameters are presented in Table 13 in chronological order for each parent molecule M. In addition to the table, we should mention the work of Dzvonik *et al.* in which several rare molecules (1-naphthyl bromide, 4-biphenyl bromide, 9-anthracyl bromide) have been studied by TOF-MS at broadband (240– 340 nm) photolysis and the β parameters have been obtained for all of them.⁹ As one can see from the table, the most studied parent molecules are HBr, IBr, and Br₂ molecules, and REMPI remains the most informative and popular detection method. To the knowledge of the author bromine atoms have not yet been detected by two-photon laser-induced fluorescence (TP-LIF).

4.2.1. Photodissociation of IBr

The photodissociation of IBr is well studied^{86,92,146,217,483,484,487-489,508} and now it is one of benchmark photodissociation processes. Note that the correlation diagram for the photodissociation of low-lying states of IBr have two crossings, the first (lowest) one changes the Br*/Br branching ratio, and the second one is responsible for the transition between the Br*+I and Br+I* energy surfaces.^{488,489}

In the wavelength range 440-685 nm, the most complete photodissociation study (the dependences of the Br*/Br branching ratio and of the anisotropy parameter β on the excitation wavelength) using the velocity map imaging technique was reported recently by Wrede *et al.*⁴⁸⁹ The β parameter dependence allowed the mapping of the partial cross sections for parallel ($\Delta \Omega = 0$) and perpendicular $(\Delta \Omega = \pm 1)$ absorptions and thus the deconvolution of the IBr absorption spectrum into contributions associated with excitation from the $X^1\Sigma^+(0^+)$ ground state to the $A^3\Pi(1)$, $B^{3}\Pi(0^{+})$ and ${}^{1}\Pi(1)$ excited states. Such analyses of the absorption spectrum of IBr, taken together with previous spectroscopic data for the bound levels supported by the A and B state potentials, has allowed the determination of the potential energy curves and transition moments to each of these excited states.

The IBr molecules initially excited to the *B* state dissociate diabatically to $I+Br^*$ and adiabatically to I+Br products.

^hBr*+H₂O \rightarrow Br+H₂O(ν_1 , ν_3).

ⁱReaction only.

^jThe deactivation rate constants are 1.1, 2.7, 3.7, 7.8, and 35×10^{-12} cm³/molecule s for T = 6, 21, 24, 36, and 48 °C, respectively.

^kBr*+HCN \rightarrow Br+HCN(001): (1.8±0.4) \times 10⁻¹¹ cm³/molecule·s.

¹The rate for the $Br^*+HCN \rightarrow Br+HCN(001)$ channel.

^mBr*+CO₂ \rightarrow Br+CO₂(ν_3): (5.6±2.8)×10⁻¹² cm³/molecule·s, 40% of the total quenching rate.

 $^n\text{Br}^*+\text{CO}_2{\rightarrow}\text{Br}+\text{CO}_2(10^01)\text{:}$ 66% of the total quenching rate.

 $^{o}Br^*+SO_2 \rightarrow Br+SO_2(\nu_1=1)/SO_2(\nu_3=1)$. ν_3 ($\Delta E = 480 \text{ cm}^{-1}$) is excited preferentially despite the existence of the more resonant ν_1 mode ($\Delta E = 270 \text{ cm}^{-1}$).

^pThe reactive rate constant for $Br^*+CH_3F \rightarrow HBr+CH_2F$ is $10^{-2.6\pm0.5} \exp[-(10100/RT)]$ cm³/molecule·s at 60–200 °C. Vibrational excitation of CH₃F accelerates the reaction Br^++CH_3F and does not influence the reaction Br^*+CH_3F .

^qObtained by absorption of the reaction product at 460–530 nm.

^aThe photolysis wavelength λ (or the range for λ) and yield of Br* (or the range for the yields) are presented. $\Gamma \sim 0$ means "below the detection limit." ^bVelocity-aligned Doppler spectroscopy (VADS) of H atoms.

^cPrivate communication from Lacombe *et al.*, the data from this work are shown by Poilly and Monnerville⁵⁰⁷ the yields of Br* are 18.6, 15.8, 15.8, 15.8, and 17.4%, the β parameters are 0.676, 0.866, 1.310, 1.204, and 1.507 for 209, 214, 220, 224.6, and 242 nm, respectively.

^dAt 235-262 and at 320-410 nm, the main products are Cl+Br* and Cl+Br, respectively.³⁸⁰

^eOnly the relative yield of Br* is obtained.

^fARA VUV was used to detect $Br(^{2}P_{3/2})$ at 148.9 nm. The yields of Br* are 7.15, 6.01, 12.9, 11.6, 20.3, 14.9, 19.0, 26.2, 36.0, 27.2, 30.0, 30.7, 29.8, 38.9, 37.4, 35.0, and 36.3% for 434, 438, 444, 448, 451, 453, 458, 463, 468, 472, 472, 477, 482, 492, 502, and 511 nm.

^gThe yields of Br* are 44, 49, 62, 67, 74, 78, 83, 84, 87, 83, 67, 61, and 40% for 445, 450, 460, 466, 470, 475, 480, 490, 500, 510, 518, 520, and 530 nm, respectively.

 ${}^{h}\beta \approx 1.5$ and 450 nm, declining to $\beta \approx 0.6$ at the longest excitation wavelength (500 nm).

 $^i The upper limits for Br_2 \rightarrow Br+Br and Br_2 \rightarrow Br^*+Br^*$ channels were below 5% and 10%, respectively.

^jThe yields of Br* are 61.3, 49.3, 38.9, 35.1, 29.9, and 28.2% for 530, 520, 510, 500, 490, and 480 nm, respectively. These Γ values present the yields of Br* from the photodissociation of IBr(B³ Π_{0+}) state only due to a parallel transition.

^kThe yields of Br* are 28, 30, 33, 36, 44, 46, 54, 62, 68, 73, 72, 71, and 68% for 450, 455, 457, 460, 465, 470, 475, 480, 490, 500, 510, 520, and 530 nm, respectively.

¹The I*+Br* channel was below the detection limit, <1%.

^mThe speed dependence of the β parameter was obtained.

ⁿVibrational and rotational state distributions for CN radicals were obtained for 193, 202, 220, 242, and 248 nm.

^oThe β parameter is 1.0±0.2 for 209.4 and 248 nm. The yield of Br* is determined for different rotational states of CN at 206.1, 209.4, 222, 248, and 260 nm. Unequal populations in the F_1 and F_2 spin-rotation components of CN have been observed.

^pRelative yields for Br*/Br were obtained by comparing the REMPI line intensities with those from the work of Cao *et al.*¹⁸⁷

^qAs the rotation qantum number for NO fragments increases from 55.5 to 61.5, the yield of Br* falls from ≈ 1 to ≈ 0.5 .¹⁸⁷

Broad band photolysis.

 $^{s}\beta = 1.86 \pm 0.15$, 1.91 ± 0.05 , and 1.94 ± 0.05 for 215.00, 220.14, and 229.22 nm, respectively.

^tThe yields of Br* atoms are 61, 54, 46, 50, 48, 47, 40, 41, 48, 54, 50, 54, 50, 46, and 46 (±5)% for 218, 220, 222.25, 220.50, 220.75, 221, 222, 223, 224, 225, 226, 230, 235, 240, and 245 nm, respectively.

^uThe β parameters for Br* atoms are 1.4 ± 0.2 , 1.3 ± 0.08 , 1.2 ± 0.2 , 1.3 ± 0.1 , and 1.2 ± 0.2 for 243.52, 251.00, 264.95, 266.71, and 277.74 nm, respectively. However, the β parameters are 1.88 ± 0.04 and 1.9 ± 0.1 at 251.00 nm for Br*+CH₃($\nu_2=0$) and Br*+CH₃($\nu_2=1$) channels, respectively.

^CAccording to Wight and Leone,⁵⁰⁶ the yield of Br* is 0.14 ± 0.04 . According to Krajnovitch *et al.*,¹³⁴ the yield of Br* and Br atoms is 0.37; hence the relative yield of Br* is 0.38 ± 0.12 .

^DBr* and Br atoms were not distinguished.

The experimentally obtained nonzero Br*/Br branching ratios are due to nonadiabatic transitions $B^3\Pi(0^+)$ $\rightarrow Y^3\Sigma^-(0^+)$, at the first (lower) curve crossing. These transitions have been well described by a one-dimensional Landau–Zener model.^{92,487,489,509}

Also, REMPI studies were reported by Jung *et al.*¹⁴⁶ and by McGivern *et al.*⁴⁸⁸ for photodissociation of IBr in the ultraviolet at 248, 266, and 304 nm. β parameters and relative probabilities have been obtained for all three product channels, Br+I, Br*+I, and Br+I*; the Br*+I* channel was not observed, because it was below the detection limit. The ultraviolet absorption spectrum of IBr has been decomposed into three components, corresponding to the ${}^{3}\Pi_{0+}$, ${}^{1}\Pi_{1}$, and ${}^{3}\Pi_{1}$ excited states. Also, nonadiabatic curve crossing probabilities for the second (upper) curve crossing have been determined for several wavelengths between 250 and 270 nm.⁴⁸⁸

4.2.2. Photodissociation of HBr

The spectrum of HBr peaking around 185 nm is assigned to a superposition of three transitions: two perpendicular $(X^{1}\Sigma^{+} \rightarrow A^{1}\Pi_{1}, a^{3}\Pi_{1}; \beta^{*} = -1)$ and one parallel $(X^{1}\Sigma^{+} \rightarrow a^{3}\Pi_{0^{+}}, \beta = 2)$. Here β^{*} and β correspond to Br^{*} and Br, respectively. The perpendicular transitions correlate to Br, while the parallel one correlates to Br^{*}.^{510,511} Another source of Br^{*} atoms is the nonadiabatic transition ${}^{1}\Pi_{1} \rightarrow {}^{3}\Sigma_{1}^{+}$ occurring at large internuclear distances. This nonadiabatic transition is unimportant at 248 nm, hence $\beta^{*}(248) \approx 2$; at 193 nm the probability of the nonadiabatic transition increases, hence the Br^{*} atoms are produced directly via $a^{3}\Pi_{0^{+}}$ state and also via the nonadiabatic transition; as a result, $\beta_{193}^{*} \approx 0$.¹⁰⁸

Note that Xu *et al.* have reported the value $\beta_{193}^* \approx -1$,⁴⁸¹ which contradicts the value $\beta_{193}^* \approx 0 \pm 0.1$ reported later by Baumfalk *et al.*¹⁰⁸ Although the result of Xu *et al.* was confirmed by calculations of Pouilly and Monnerville,⁵¹² we recommend the result of Baumfalk *et al.*: one can easily see from Fig. 3 of paper of Xu *et al.*, that in reality the value β_{193}^* was measured with very large uncertainty, $\approx -1 \pm 1$; hence, there is no large contradiction.

Only a few theoretical studies exist concerning the photodissociation of HBr. Predictions on the wavelength dependencies of the β parameter and the ratio Br*/Br for vibrationally excited HBr(v=0,1,2) are presented by Poilly *et al.*^{512,513}

4.2.3. Photodissociation of Br₂

The absorption spectrum of Br_2 has continuous bands with two peak maxima at 225 and 420 nm; the correlation diagram is given, for example, by Jung *et al.*⁴⁸⁶

Photolysis of Br₂ near $\lambda = 500$ nm produces nearly equal proportions of Br and Br^{*} via the repulsive limb of the $B^3\Pi_u(0^+_u)$ electronic state. The quantum yield of Br^{*} peaks at 87% for $\lambda = 500$ nm and decreases to 30% at $\lambda = 440$ nm due to the absorption to the repulsive ${}^{1}\Pi_u(1_u)$ state.⁴⁸⁴ The experimental yields of Br^{*} are in excellent agreement with the calculations of Le Roy *et al.*,⁵¹⁴ except for the longwavelength region.

Jung *et al.* have found that the spectrum around 225 nm is mainly due to the perpendicular transition $X^{1}\Sigma_{g}^{+}$ $\rightarrow^{3}\Sigma_{u}^{+}(1_{u})$, which produces Br*+Br products.⁴⁸⁶ The small relative contribution of the parallel component was found to be $X_{\parallel}=0.07$ from the standard relationships $\beta=\beta_{\parallel}X_{\parallel}+\beta_{\perp}X_{\perp}, X_{\parallel}+X_{\perp}=1$, where $\beta_{\parallel}=2$ and $\beta_{\perp}=-1$.

4.3. Production of Br* Atoms in Chemical Reactions and *V*-*E* Energy Exchange Processes

4.3.1. Reactions of I* and F* Atoms with Br₂

Since the production of X* atoms in chemical reactions has been reviewed by Dagdigian,⁵ here we discuss only some doubtful processes. No Br* atoms have been observed by Argawalla *et al.* in the reaction of F*/F atoms with Br₂,⁵¹⁵ which puts in doubt the results of experiments with photodissociation of WF₆ and UF₆ of Gordon *et al.*,⁹⁷ in which quick reaction F*+Br₂ \rightarrow BrF+Br* was assumed.

Also, there is some doubt concerning the deactivation of I^* by Br_2 ,

$$I^* + Br_2 \rightarrow Br^* + IBr, \qquad (32a)$$

$$\rightarrow$$
 Br+IBr, (32b)

$$\rightarrow$$
I+Br₂. (32c)

According to Hofmann and Leone, the probability of channel (32a) is $15\pm5\%$ only.²⁰⁴ Since a large yield of Br* atoms was confirmed in several studies (see Table 14) that is, $k_{32a} \gg k_{32b}$, the main process must be the physical quenching channel (32c). But, according to Wiesenfeld and Wolk,⁴⁶⁹ the probabilities of channels (32a), (32b), and (32c) differ from that, they are $72\pm18\%$, $18\pm18\%$, and $10\pm10\%$, respectively. Hence, the deactivation of I* with Br₂ occurs mainly via an adiabatic reaction leading to Br*+BrI. These last data have been confirmed by Gordon *et al.*, who measured the

^vThe β parameters were measured for Br(²P_{1/2}, ²P_{3/2}) atoms. Most of the atoms are assumed to be in ²P_{1/2} state.

^wThe yields of Br* atoms are 9, 16, and 14 (\pm 10)% for 267, 261.5, and 248.5 nm, respectively; the β parameters for Br* atoms are 1.5, 1.4, 1.4, 1.4, and 1.3 (\pm 0.2) for 248.5, 262.5, 264.9, 266.7, 268.8 nm, respectively.

^AThe probabilities of CF₂Cl+Br*/Br and CF₂Br+Cl*/Cl channels are 0.96 and 0.04±0.1, respectively.

^BThe absolute yield of Br* is shown.

^bHowever, the contribution from $HF(v = 1) + Br \rightarrow Br^* + HF$ cannot be ruled out.⁵²³

^cBr* atoms detected, but the yield is not measured.

^dAnalysis of the infrared emission from I* atoms. The fractions of the total deactivation rate constants attributed to the reactive channel I*+ $M \rightarrow Br^*$ +M' are 15±5 and 13±5%, for M=Br₂ and IBr, respectively.

^eBr₂^{*} denotes Br₂(B ³ $\Pi_{0_{\mu}^{+}}$). The rate constants for Br₂^{*}+M \rightarrow Br^{*}+Br+M are 2.9, 1.2, and 0.54, all in 10⁻¹⁰ cm³/molecule s units, for M=Br₂, Xe, and Ar, respectively.

probabilities for these channels to be 79 ± 10 , 13 ± 10 , and $8\pm3\%$, respectively.⁹⁷ These last two sets of data are preferable.

4.3.2. V-E Energy Exchange

The rate constant for the production of Br* atoms in energy exchange process

$$Br + HF(v=1) \rightarrow Br^* + HF(v=0)$$
(33)

was determined by Quigley and Wolga,⁵¹⁶ from the analysis of the kinetics of HF(v=1) fluorescence, and a value of $k_{33} = (3.1 \pm 1.5) \times 10^{-12} \text{ cm}^3/\text{molecule} \cdot \text{s}$ has been reported. The same method was used and almost the same value, $k_{-33} = (3.4 \pm 0.6) \times 10^{-12} \text{ cm}^3/\text{molecule} \cdot \text{s}$, was obtained later by Wodarczyk and Sakett for the reverse process.⁴⁶¹ The rate constant for the direct process (33) is related to the rate constant for the reverse process through the detailed balance relation,

$$k_{-33}/k_{33} = (g_{3/2}/g_{1/2})\exp(\Delta E/kT),$$
 (34)

where g_J is the degeneracy of the ${}^{2}P_J$ state, and $\Delta E = -277 \text{ cm}^{-1}$ is the defect of resonance. Substituting the appropriate values, one finds $k_{-33}/k_{33}=0.53$, hence the detailed balance is obeyed within a factor of 2.⁴⁶¹

The energy exchange process

$$Br + HBr(v=1) \rightarrow Br^* + HBr(v=0)$$
(35)

was studied by Karny and Katz⁵¹⁷ who observed IR emission from Br*, and by Donovan *et al.*,⁵¹⁸ who used ARA VUV. The rate constants have been found as $(2.2\pm0.2)\times10^{-14}$ and $(1.6\pm0.7)\times10^{-12}$ cm³/molecule·s, respectively. Since the work of Donovan *et al.* is indirect, and the authors of this work claim that the data for process (35) are less accurate than their other data, the data of Karny and Katz are preferable. Note also, that the rate constant for process (35) may be calculated from the detailed balance relation by using the rate constant for the reverse process obtained by Leone and Wodarczyk,⁴⁶² $k_{-35} = (7.1\pm3.5)\times10^{-13}$ cm³/molecule·s. Surprisingly, this calculated rate constant is 200 times smaller than the rate constant of Karny and Katz.⁵¹⁷

5. Excited lodine Atoms $I^*({}^2P_{1/2})$ 5.1. Collisional Deactivation of I* Atoms at T=300 K

The rate constants for the collisional deactivation of I^* at room temperature are listed in Tables 15 and 16 in chronological order for each quencher M.

5.1.1. Deactivation of I* by Halogen and Interhalogen Molecules

The rate constants for I^{*} deactivation by Br_2 , Cl_2 , IBr, and ICl reported by Donovan, Hathorn, and Husain⁴⁷² by the ARA UV method differ significantly from the rate constants determined by several other groups who used several different methods. This disagreement may probably be explained by an excess of I^{*} atoms in the study of Husain *et al.*²⁰⁴

Hofmann and Leone have proposed that the deactivation of I^{*} by I_2 , Br_2 , Cl_2 , IBr, ICl, and BrCl occurs mainly via reaction through the formation of a collisional intermediate complex. Basic properties of these trihalogen complexes are:

(A) complexes containing iodine are more stable than those containing only bromine and chlorine,

(B) the presence of chlorine atoms decreases the stability of the complex,

(C) the most stable configuration has the most electropositive atom (I>Br>Cl) in the central position.²⁰⁴

5.1.2. E-V Energy Transfer: I*+HF

Coombe and Pritt have determined the fraction of the total quenching of I* by HF that occurs due to E-V energy exchange processes¹²¹

$$I^* + HF(v=0) \rightarrow I + HF(v=2) + 146 \text{ cm}^{-1}$$
, (36)

$$I^* + HF(v=0) \rightarrow I + HF(v=1) - 3641 \text{ cm}^{-1}$$
. (37)

^aThe rate constants from two studies^{112,531} were multiplied by 16/5.7 (see text). ^bThe main channel is $I^*+I+M \rightarrow I_2^*(B^3\Pi_0^+)+M$, followed by chemiluminescence.

^cThe main channel is $I^*+I+M \rightarrow I_2^*({}^{3}\Delta_{1u})+M$, followed by chemiluminescence at around 655–685 nm.

^dThe temperature dependence of the deactivation rate constant at 295–410 K is obtained (see Table 17).

eThe rate constant was extrapolated from shock tube experiments at 1200-3500 K.

^fThe rate constant is wrong because of an error in the HF concentration determination, it has been remeasured in Pritt and Patel.⁵⁴⁰

^gThe vibrational distribution of CO is 1.00:0.094:0.043 (v = 1, v = 2, v = 3).⁵⁶³

^hThe fractions of the reactive channel are 0.96 ± 0.12 and 0.94 ± 0.13 for HBr and DBr, respectively.

ⁱA weak negative temperature dependence of the deactivation rate constants at T = 253 - 427 K was obtained.

^jAccording to Deakin *et al.*,⁵⁴⁸ this rate constant is incorrect due to the contribution of the $I+O_2(^{1}\Delta) \rightarrow I^*+O_2$ process.

^kThe physical quenching rate constant was determined to be $(0.9\pm4)\times10^{-12}$ cm³/molecule·s.

¹Quenching rate constants at 295–600 K are obtained.

^mThis value is incorrect because of the nonstatistical population of the F=2,3 hyperfine sublevels of I* atoms obtained by photolysis of I₂ at 498 nm.¹⁴⁷ ⁿInfrared emission from O₂(¹S) was detected.

^oOnly the channel leading to $O_2({}^{1}\Sigma)$ +I. The rate constants are 0.9, 1.1, 1.2, and 1.3 in 10^{-13} cm³/molecule s units for T=268, 298, 320, and 353 K. ^pPrivate communication of Houston, published in Lilenfield *et al.*⁵⁶

 $^{q}90\pm10\%$ of the I*+Br₂ collisions result in chemical reaction, the yield of Br* is 80%.

^rThe deactivation of I^{*} by I₂ results in vibrationally excited $I_2^*(X,25 \le v \le 43)$.⁵⁶⁴ It is interesting that this excited I_2^* molecule may be dissociated by further energy transfer from O₂(¹ Δ) on subsequent collisions.⁵⁶⁵

^sThe quenching rate constant is given by the expression $8 \cdot 10^{-11} \exp(-4.4 \cdot T/1000) \text{ cm}^3/\text{molecule} \cdot \text{s}$ (T = 293 - 1000 K).

^aThe rate constants from two studies^{112,531} were multiplied by 16/5.7 (see text).

^bRelative measurement (see text).

 $^{\rm c}T = 453$ K.

^dThe temperature dependence of the deactivation rate constant at 295-410 K is obtained, see Table 17.

^cThis value is obtained in 100 Torr of Ar, at T=25 °C. The values in Ar, N₂, and CO₂ at different pressures and temperatures are also presented.

^fRelative measurement, the reference process is the deactivation of I* by I₂ for which we assumed the rate constant of 3.4×10^{-11} cm³/molecule·s. The H atom abstraction reaction rate constant is also measured.

^gThe fractions of the reactive channel are 0.03 ± 0.11 and 0.03 ± 0.16 for CH₄ and C₃H₈, respectively.

^hThe result is controversial.⁵⁷⁶

ⁱThe reaction rate constant is estimated as $(1\pm0.6)\times10^{-14}$ cm³/molecule·s at T=316-447 K.

^jThe reaction channel is <0.01 of the total quenching.

^kThe I^{*}+C₃F₇I \rightarrow I₂+C₃F₇ reaction rate constant is found to be $\leq (3 \pm 1.5) \times 10^{-19}$ cm³/molecule s.

For example, the rate constant for channel (36) has been found to be $(9.63\pm4.0)\times10^{-13}$ cm³/molecule·s. Since the total deactivation rate constant for I^{*} by HF was assumed to be about 3×10^{-12} cm³/molecule·s, ^{538,539} it was concluded that the fractions are 0.35 ± 0.04 for channel (36) and 0.05 ± 0.04 for channel (37); hence ~60% of the deactivation of I^{*} by HF occurs via *E-R*, *T* energy transfer.

However, later the total deactivation rate constant has been remeasured and a new, more correct value [(8.9 ± 0.1) $\times10^{-13}$ cm³/molecule·s] has been obtained.⁵⁴⁰ Thus, the conclusion has been changed: deactivation of I* by HF occurs mainly via *E-V* energy exchange through channels (36) and (37) and the role of *E-R*, *T* channels is very small.

5.1.3. Recombination Reactions of Excited I* Atoms

From spectroscopic and kinetic arguments Stephan-Rossbach and Comes have concluded that the trimolecular recombination of excited I* atoms proceeds mainly via two pathways,

$$I({}^{2}P_{3/2}) + I({}^{2}P_{1/2}) \to I_{2}^{*}(B^{3}\Pi_{0}^{+}) \to I_{2}(X) + h\nu_{1}, \quad (38)$$

$$I({}^{2}P_{1/2}) + I({}^{2}P_{1/2}) \xrightarrow{+M} I_{2}^{*}({}^{3}\Delta_{1u}) \longrightarrow I_{2}(X) + h\nu_{2}.$$
(39)

While the chemiluminescence spectrum for reaction (38) is broad, it lies at $\nu_1 > 500$ nm and has a maximum at ~560 nm,^{136,148} the chemiluminescence spectrum for reaction (39) is narrow: 655 nm $< \nu_2 < 685$ nm.¹³⁶ The trimolecular rate constant for reaction (38) is determined by the LIF VUV method to be $(1.0 \pm 0.5) \times 10^{-32}$ cm⁶/molecule² · s for M=C₃F₇I and in the limit of low pressure.^{148,597} An upper limit of the rate constant for a possible bimolecular reaction of I* with *n*-C₃F₇I yielding I₂(X¹\Sigma⁺_{og}) was found to be $(3\pm 1.5) \times 10^{-19}$ cm³/molecule · s.⁵⁹⁷

Andreeva et al. have estimated the rate constant to be $\leq 2 \times 10^{-33} \text{ cm}^6/\text{molecule}^2 \cdot \text{s}$ from a rather complicated modeling of experiments in which I2 was detected by timeresolved visible spectrometry after the photolysis of CF₃I.¹¹⁴ The same method was used by Kuznetsova and Maslov⁵⁸⁸ to determine the recombination rate constants $I^* + R \rightarrow RI$, for which the values of (1.2-4), (0.42-3.5), and (0.18-1.4), all in $10^{-12} \text{ cm}^3/\text{molecule} \cdot \text{s}$, have been obtained for R = CF₃I, n-C₃F₇I, and i-C₃F₇I, respectively. Note that these rate constants are 1 order of magnitude lower than the rate constants for the $I+R \rightarrow RI$ recombination processes. This seems to be a general rule: the excited I* atoms recombinate slower than ground state I atoms. The method of quantitative laser induced chemiluminescent kinetic spectroscopy was developed by Egorov et al. for the study of chemiluminescence reactions.⁵⁹⁸ This method was used to obtain spectral distributions of chemiluminescence rate constants and total chemiluminescence rate constants for processes (38) and (39).

Also, the bimolecular photorecombination reaction followed by chemiluminescence

$$({}^{2}P_{1/2}) + R \rightarrow RI({}^{3}Q_{0}^{+A}) \rightarrow RI(X) + h\nu,$$
 (40)

where $R=C_3H_7$ and $R=CF_3CFCF_3$ has been observed by Pravilov *et al.*⁵⁹⁹

5.1.4. Chemical Trapping: I*+NOCI→NO+ICI

One of the first methods to study the processes of I* atoms was the chemical trapping method, which was developed by Pravilov *et al.*^{122,570,584,593,600–604} The method is based on the competition of the reaction

$$I^* + NOCl \rightarrow NO + ICl,$$
 (41)

and the physical quenching of I* atoms by some other molecules, for example, by C_3H_8 (a), C_3H_6 (b), C_4H_8I (c), and $CH_{3}I$ (d); the quenching rate constants are denoted here k_{a} , k_h , k_c , and k_d , respectively. Note that the physical quenching $I^* + NOCI \rightarrow I + NOCI$ and the reaction $I + NOCI \rightarrow NO$ + ICl are slow, so that they can be neglected. 122,593 Relative measurements gave the ratios $k_{41}/k_a = (5 \pm 3) \times 10^3$, $k_{41}/k_b = (5 \pm 4) \times 10^3$, $k_c/k_{41} = (0.5 \pm 0.2) \times 10^{-3}$, and $k_d/k_{41} = (2.1 \pm 0.5) \times 10^{-3}$. ^{570,593} The rate constant k_d is well established now to be $(2.6 \times 10^{-13} \text{ cm}^3/\text{molecule} \cdot \text{s})$, so from the ratio k_d/k_{41} we can calculate the rate constant $k_{41} = (1.24 \pm 0.3) \times 10^{-10} \text{ cm}^3/\text{molecule} \cdot \text{s.}$ Using this value, we can calculate the rate constants $k_a = (0.25^{+0.4}_{-0.10}) \times 10^{-13}$, $k_b = (0.25^{+1.0}_{-0.12}) \times 10^{-13}$, and $k_c = (6.2 \pm 3) \times 10^{-11}$ and $k_c = (6.2 \pm 3) \times 10^{-11}$ $cm^3/molecule \cdot s$; these values are presented in Table 16. These values contradict the data obtained in 1969 by Donovan et al.,³²⁸ and by Hathorn et al.,⁵⁶⁸ but the reason for the disagreement is unclear.

5.1.5. Temperature Dependence of Deactivation Rate Constants

The temperature dependence of deactivation rate constants for I* atoms by various molecules were determined by Callear and Wilson (H₂, I₂, N₂, C₂H₆, and C₃H₈, 30–90 °C),^{112,531} by Broadbent and Callear (CH₄, C₂H₆, C₃H₈, and *n*-C₄H₁₀, 303–373 K),⁵⁷² by Deakin and Husain (H₂, D₂, N₂, O₂, I₂, CH=CH, CH₄, CH₂=CH₂, C₂H₆, C₃H₈, CH₃CH=CH₂, *n*-C₄H₁₀, 180–410 K),⁵³⁴ by Kartazaev *et al.* (I₂, 295–1000 K),⁵⁶¹ by Fotakis and Donovan (HBr, 253–427 K),⁵⁴⁴ by Cline and Leone (I₂, 300–800 K),⁵⁶² by Burde *et al.* (O₂ and I₂, 295–600 K),⁵⁵² and by Van Marter and Heaven (O₂, 150 K).¹⁴⁷ Arrhenius parameters for the deactivation of I* atoms by various molecules are presented in Table 17, some of them have been calculated in the present review.

Several deactivation rate constants were determined by Callear and Wilson at 30, 60, and 90 °C.^{112,531} This was an indirect study, in which the products of the $C_3H_8+I_2$ photolysis by visible light were analyzed by gas chromatography. The rate data from Callear and Wilson were determined relative to the $I^* + C_3H_8$ rate constant of Donovan and Husain $(k' = 5.7 \times 10^{-14} \text{ cm}^3/\text{molecule} \cdot \text{s})$.^{526,530} In Tables 15, 16, and 18 we present the rate constants of Callear and

^dPrimary H atom abstraction reaction rate constant.

Wilson multiplied by k''/k' = 16/5.7, since the last and more correct rate reported by Wiesenfeld and Wolk is $k'' = 1.6 \times 10^{-13} \text{ cm}^3/\text{molecule} \cdot \text{s.}^{119}$

5.1.6. Deactivation of I* by O₂

The deactivation of excited I* atoms by ground state $({}^{3}\Sigma)$ oxygen occurs mainly via the near-resonant energy exchange process

$$\mathbf{I}^* + \mathbf{O}_2(X^3\Sigma) \longrightarrow \mathbf{I} + \mathbf{O}_2({}^1\Delta). \tag{42}$$

The physical quenching $I^* + O_2(X) \rightarrow I + O_2(X)$ is found to be insignificant.^{234,605} The reverse process

$$\mathbf{I} + \mathbf{O}_2({}^1\Delta) \longrightarrow \mathbf{I}^* + \mathbf{O}_2(X^3\Sigma), \tag{43}$$

^aReaction rate constants.

is also quick, $k_{43}/k_{42}=2.94$ at room temperature.²³⁴ These forward and reverse rate constants have been measured at room temperature^{234,534,550,552} and at T=150 K.^{147,553}

The temperature dependence for the rate constant k_{43} was determined at 180–410 K by Deakin and Husain.⁵³⁴ The activation energy of the deactivation process (43) was found to be 0.2 ± 0.2 kcal/mol, less than the exothermicity of the process. To explain this finding, Deakin and Husain suggested that the rate constant may be inversely dependent on temperature. Since then, it is a common practice to model the temperature dependence for the rate constant using expressions

$$k_{42} = A_{42} \exp(-T_{42}/T), \qquad (44)$$

$$k_{43} = A_{43}(T_{43}/T), \tag{45}$$

where $A_{43}=7.8\times10^{-11}$ cm³/molecule·s, $T_{43}=295$ K, $A_{42}=10.4\times10^{-11}$ cm³/molecule·s, and $T_{42}=401.4$ K. However, the last measurements of van Marter and Heaven $(k_{42}=7.0\times10^{-12}$ cm³/molecule·s at T=150 K)¹⁴⁷ disagree both with the predictions of the Arrhenius expression reported by Deakin and Husain $(k_{42}=1.8\times10^{-11}$ cm³/molecule·s at T=150 K) and expression (44) $(k_{42}=1.4\times10^{-11}$ cm³/molecule·s at T=150 K). Hence, the temperature dependencies of the rate constants for these processes remain unclear.

Long-range multipolar interactions or nonadiabatic surface crossings are usually suggested to be responsible for the energy transfer between small molecules. Kaledin *et al.* have calculated potential energy surfaces for all states correlating with the $I+O_2(^{1}\Delta)$ and $I^*+O_2(X)$ dissociation limits using high-level *ab initio* methods.^{606,607} Long-range attractive forces were found to be relatively weak, with no state bound by more than 250 cm⁻¹. Hence the energy exchange process (43) is likely due to the surface crossings, and thus the rate constant for this process must have a positive temperature dependence. This prediction is in agreement with the experimental data.^{147,534}

The deactivation of I^{*} atoms by excited $(^{1}\Delta)$ oxygen also occurs mainly via the near-resonant energy exchange process,

$$\mathbf{I}^* + \mathbf{O}_2(^1\Delta) \longrightarrow \mathbf{I} + \mathbf{O}_2(^1\Sigma), \tag{46}$$

suggested by Ogryzlo *et al.*⁶⁰⁸ and studied by Heidner *et al.*⁵⁵⁴

5.1.7. Theoretical Considerations

The first quantum-mechanical study of the collinear reaction $I^* + H_2$ were done by Zimmerman and George.^{277,609,610} Later, using the analogy with the related Xe+H₂ system, Resnikov and Umanskii estimated the long-range interaction potential for $I^*/I+H_2$ and carried out a calculation for the $I^* + H_2$ quenching processes.²⁶⁸ The Landau–Zener formula with quadrupole-quadrupole interaction as a perturbation was used. It was found that the main contribution comes from *E-V* energy exchange $I^* + H_2(v) \rightarrow I+H_2(v')$ where v=0,1,2 and v'=v+2. The temperature dependence of the rate constants for the deactivation of I^* by H_2 was found to be in excellent agreement with experiment, while the absolute value was four times smaller. Since no fitting parameters were used in the model, this agreement may be called satisfactory.

5.2. Production of I* Atoms by Photolysis

A great deal of work has been done on the photodissociation of iodine-containing compounds, see reviews of Okabe,⁶¹¹ Pravilov,⁶¹² Jackson and Okabe,⁶¹³ and Hirota.⁶¹⁴ The data for β parameters and relative quantum yields of I* atoms for the photodissociation of small (up to seven atoms) and large (more than seven atoms) parent molecules M are presented in Tables 19 and 20, respectively, in chronological order for each molecule M. Several broad-band studies are not mentioned here; however, the work of Dzvonik *et al.* should be mentioned, since several rare molecules (phenyl iodide, 1-naphthyl iodide, 2-naphthyl iodide, 4-biphenyl iodide, 3-biphenyl iodide) have been studied by TOF-MS at broadband (240–340 nm) photolysis and the β parameters have been obtained for all of them.⁹

5.2.1. Correction of the I* Yield in the Photolysis of n-C₃F₇I

One of the most efficient photolytical sources of I* atoms is $n-C_3F_7I$, which has a very large yield of I* atoms at 205-315 nm. Until recently, the yield of I* atoms at 266 nm was expected to be unity, based on the infrared luminescence measurements of Ershov et al. $(97.8 \pm 1.2\%)^{123}$ and the diode laser absorption study of Hess et al. $(102\pm4\%)$.¹³⁷ However, Alekseev et al. have found that in reality this yield is lower, it is $\approx 92\%$.⁵⁸⁴ This conclusion was confirmed recently in two works. The ground state I atoms have been observed in the photodissociation of n-C₃F₇I by Kavita and Das $(\Gamma = 83 \pm 2\%)^{196,665}$ and by Baklanov *et al.* $(\Gamma = 92 \pm 1\%)$,¹⁴⁵ who used two-photon LIF and REMPI (1+1'), respectively. Baklanov *et al.* have pointed out that the yield of I* atoms in the study of Ershov et al. has probably been overestimated due to the formation of exciplexes $I^*-C_3F_7I$, since the formation of these exciplexes should result in an increase of the radiative transition rate of I* atoms.669 Also, Baklanov et al. have noticed that the yield of I* atoms in the study of Hess et al. was probably overestimated due to the uncertainty in the results of the decomposition of the experimental kinetics into a sum of two exponents in the case where the rise and fall times of the kinetics are very comparable.

Note that the photodissociation of n-C₃F₇I has been used as a reference source with unity yield of I* atoms in a series of measurements.^{94,126,547,555,571,655,656,668,669} Now, all the results of these measurements should be recalculated, and the reported yield of I* atoms should be decreased.

5.2.2. Photodissociation of HI and DI

According to Mulliken's prediction, ⁵¹⁰ the first absorption continuum (A-X band: 190–300 nm, peaks at 220 nm) of HI consists of the following transitions to the three upper states of the Q-group:

$$HI({}^{1}\Sigma_{0}^{+}) + h\nu \rightarrow HI({}^{3}\Pi_{1}, {}^{1}\Pi_{1}) \rightarrow H + I({}^{2}P_{3/2}),$$

$$\Delta\Omega = \pm 1 \quad (\beta = -1), \qquad (47a)$$

$$HI({}^{3}\Pi_{0}) \rightarrow H + I^{*}({}^{2}P_{1/2}), \quad \Delta\Omega = 0 \quad (\beta = 2), \qquad (47b)$$

and the strongest transition must be ${}^{1}\Pi_{1} \leftarrow {}^{1}\Sigma^{+}$. Mulliken also predicted that, at the equilibrium bond length of the ground state of HI, the highest in energy in the ${}^{1}\Pi_{1}$ state, and the lowest is the ${}^{3}\Pi_{1}$ state, with ${}^{3}\Pi_{0}$ in the middle. Hence one would expect that the I* production due to the parallel transition would peak in the middle of the *A* band, or at the red end of the *A* band. Later De Vries and co-workers suggested that I* is produced not only by the parallel transition (47b), but by the perpendicular HI(${}^{1}\Sigma_{0}^{+}$) \rightarrow HI(${}^{3}\Sigma_{1}^{+}$) transition also.⁶¹⁶ This suggestion is discussed in detail, for example, by Langford *et al.*⁶²⁰

The studies on the yield of I* atoms from the photolysis of HI has been reviewed recently by Regan *et al.*⁶²¹ In this analysis the early data^{526,545,581,682,683} were omitted. Also, the results of Langford et al. have been recalculated, since in the measurements of Langford et al. the H atoms were detected by the H-Rydberg atom time-of-flight technique (HR-TOF) and the bandwidth of the probe laser was too narrow. The Monte Carlo modeling of these HR-TOF experiments gave new values for the yields of I* atoms, presented in footnotes to Table 19. Finally, there exists good agreement between all available data on the yield of I* atoms from photodissociation of HI.⁶²¹ However, later Manzhos et al.⁶²² have determined by photofragment imaging technique that the yields of I* atoms are consistently lower than the ones obtained by Regan et al.⁶²¹ The experimental data were used for the reconstruction of potential energy curves of HI molecule using three-potential^{149,615,622} and four-potential^{92,622,684} fits.

There are several theoretical predictions on the photodissociation of HI in the literature.^{615,685,686} In the most recent treatment of Balakrishnan *et al.*,⁶⁸⁶ the wavelength dependence of the I*/I branching ratio is in good agreement with the experimental data.

Also, in the recent study of Jodoin and Brown the angular distribution of iodine atoms have been calculated, and the orientation and alignment parameters $a_Q^{(K)}(p)$ were predicted.⁶⁸⁷

5.2.3. Photodissociation of ICN

In the linear geometry, three excited states, ${}^{3}\Pi_{0^{+}}$, ${}^{3}\Pi_{1}$, and ${}^{1}\Pi_{1}$, are involved in the photodissociation of ICN in the *A*-*X* band continuum (210–340 nm). A conical intersection between the ${}^{3}\Pi_{0^{+}}$ and ${}^{1}\Pi_{1}$ surfaces causes nonadiabatic coupling, and as a result, both of these surfaces may lead to the I* product. In bent geometries, the doubly degenerate

TABLE 19. Summary of I* relative quantum yield and β parameter determinations from photodissociation of small molecules

^aThe photolysis wavelength λ (or the range for λ) and the yield of I* (or the range for the yields) are present. $\Gamma \sim 0$ means "below the detection limit." ^bRelative values, reference process is the photodissociation of n-C₃H₇I.

^cVelocity-aligned Doppler spectroscopy (VADS) of H atoms.

^dThis is a value corrected later by Langford *et al.*⁶²⁰

^eThe recalculated yields of I* are 14.9, 24.8, 30.7, 31.8, 38.9, 41.8, 48.1, 51.1, 52.2, 53.1, 54.1, 50.2, 47.1, 43.9, 42.0, 34.0, 23.9, 17.0, 13.0, 5.9, and 3.0% for 208, 213, 218, 222, 228, 233, 235, 238, 243, 248, 253, 258, 260, 263, 266, 278, 283, 287, 293, 298, and 303 nm, respectively (see text). These data are taken from Fig. 3 of paper of Regan *et al.*⁶²¹

^fThe β parameters are 2.0, 1.8, 1.8, 1.9, and 1.9 (all ± 0.3) for 208, 222, 233, 243.6, and 266 n, respectively.

^gThe yields of I* are 38.2±1.1, 44.9±1.8, 49.7±2.0, 45.6±0.6, 40.5±0.9, 36.0±0.6, 28.4±0.9, 24.7±5.0, and 23.9±1.1% for 266, 257, 248, 240, 232.5, 225, 216.7, 215, 212.5 nm, respectively.

^hThe yields of I* are 35.0, 50.2, 49.5, 44.1, and 24.2% for 222, 248, 258, 266, and 280 nm, respectively. These data are taken from Fig. 2 of paper of Regan *et al.*⁶²¹

ⁱThe yields of I* are 11±1, 14±1.3, 16, 14.6±1.5, 18.8±0.4, 19.5±0.2, 22.5±3, 23.2±1.3, 23, 23±0.1, 27.5±0.2, 28.4, 26.3±0.2, 29.1±1, 31.8 0.5, 20.8±0.1, and 34.5±2% for 288, 287, 286, 285, 284, 283, 282, 281, 280.2, 280, 279, 278, 277.92, 271, 275, 274, and 273 nm, respectively. ^jPaper of Betts⁶²³ is unavailable for the author. The data are taken from paper of Clear *et al.*⁶¹⁵

^kFrom the analysis of angular and velocity distributions of Cl^{*} and Cl it was concluded that there are only two channels: $ICl \rightarrow I^* + Cl$, $Cl^* + I$. Hence β for I^{*} is assumed to be equal to β of Cl.

¹The I* +Br* channel was below the detection limit, <1%.

^mThe yields of I* are 46, 44, and 31% for 479.6, 464.9, and 449.8 nm, respectively.

ⁿThe yield of I* at 483.5 nm was assumed to be 0.5. The relative measurements gave the yields of I* of 44 ± 2 , 33 ± 1 , and $8\pm3\%$ for 502.0 ± 1.5 , 515.5 ± 1.5 , and 533.0 ± 4 nm, respectively; all at T=373 K.

^oThe yields of I* are 49.7, 50.5, 48.2, 49.7, 51.2, 50.5, 49.2, 44.4, 29.1, 15.3, 9.9, and 4.8 for 470, 475, 480, 485, 490, 495, 500, 505, 510, 515, 520, and 525 nm, respectively.

^pThe yields of I* are 16.3, 21.3, 24.2, 27.3, 28.6, 30.7, 31.3, 33.3, and 34.1% for 460, 470, 475, 480, 485, 490, 492, 495, and 498 nm, respectively.

^aThe yields of I* are 29±6, 41±3, 62±2, 64±3, 68±2, and 27±3% for 457.9, 476.5, 488.0, 496.5, 501.7, and 514.5 nm, respectively.

The yields of I* are 32 ± 4 , 35 ± 9 , 51 ± 3 , 68 ± 2 , 60 ± 2.2 , 45 ± 2 , 19 ± 1 , and $11\pm1\%$ for 280, 277.5, 270, 266, 262, 258, 246.9, and 239.5 nm, respectively. The yields of I* are obtained from molecular beam experiments with cold ICN (*T*=3.2 K). The yields of I* from room temperature ICN are 65 ± 10 , 61 ± 17 , and $44\pm12\%$ for 266, 280, and 290 nm, respectively.

^tFrom summation of the Doppler resolved CN rotational state distribution.

"The yields of I* are 53.4±2, 57.7±2, 62.9±2, 64.5±4, 66±2, 62.5±3, and 44.0±4% for 284, 280, 276, 272, 266, 260, and 248 nm, respectively.

"The β parameters and I*/I branching ratios are obtained as a function of the CN(v=0) rotational state.

^wFor 266 nm, the I*/I branching ratio is in good agreement with the value of Wittig et al.⁶³¹

^xVelocity and β parameters of the CN photofragment are determined for both I* and I channels; a Ti:sapphire ring laser was used.

^yThe polarization ratio is obtained as a function of the electric field strength.

^zThe I* quantum yield is obtained as a function of CN rotational state.

^AThe yield of I* decreases smoothly from 50% at 270 nm to 1% at 320 nm.⁵⁷¹ A femtosecond study of the photodissociation of IHgI is presented by Dantus *et al.*⁶⁷²

^BThe yields of I* are 59, 63, 75, 47, and 21% for 245.5, 250.6, 275, 292, and 308 nm, respectively.

^CThe data of Pence *et al.*⁹⁴ have been corrected by Smedley and Leone:⁶⁶⁹ Γ =4 and 21% for 308 nm photodissociation of CH₃I of CH₂I₂, respectively.

^DThe yields of I* are 19.2, 49.1, 76.5, 78.4, 63.7, and 59.2% for 310, 295, 276, 267, 251, and 244 nm, respectively.

^EThe yields of I* are 59 ± 4 , 60 ± 4 , 76 ± 9 , 48 ± 5 , and $19\pm4\%$ for 247.5, 251.5, 275.5, 296.0, and 312.5 nm, respectively.

^FThe yields of I* are 91 ± 30 , 24 ± 30 , 48 ± 15 $24\pm15\%$ for 210-187, 180-162, 162-158, 158-155 nm, respectively.

^GThe vibrational population in the CH₃ mode ν_2 is determined.

^HThe I/I* ratios are <0.05, 0.09, 0.19, and 0.68 for the ν_2 =0-3 vibrational modes of CD₃ from photodissociation of CD₃I, and 0.08, 0.37, and 1.1 for the ν_2 =0-2 modes of CH₃ from photodissociation of CH₃I.

^JThe yield of I* is $\sim 10\%$ for the parallel transition, an it is below the detection limit for the perpendicular transition.

^KEstimates by the pinhole-field deflection method gave a ratio $\sigma_{\perp}/\sigma_{\parallel}$ of 0.00–0.10 at 266 nm and 0.20–0.30 at 304 nm.

^LKang *et al.* reported the yield of I* to be 30%, but the value has been recalculated by Eppink and Parker.¹⁸⁵ (CH₃I)_n clusters have also been observed by Kang *et al.*

^MThe yields of I* are 94, 83, and 51% for the $\nu_2 = 0$, 1, and 2 vibrational states of CH₃; however, the authors estimate these data to be too uncertain.

^NThe yields of I* are 62±4, 70±5, 73±9, 67±8, 48±5, and 8±7% for 247.5, 251.5, 274.0, 280.5, 296.0, and 312.5 nm, respectively.

^oThe yields of I* are 47 ± 2 , 51 ± 1 , 51 ± 2 , 55 ± 3 , and $38\pm1\%$ for 222, 236, 266, 280, and 304 nm, respectively.

^PHere the average yield of I* atoms over the A-band (200–350 nm) is given. The dependence of the yield on the wavelength is presented in Fig. 4 of paper of Ivanov *et al.*⁶⁰²

 Q The yields of I* are 65±4, 78±5, 63±6, 44±7, 36±3, and 21±3% for 247.5, 274.0, 287.5, 296.0, 301.5, and 312.5 nm, respectively.

^RThe yields of I* are 47±25, 86±13, 91, 91±9, 107±14, and 75±25% for 234, 246, 266, 283, 299, and 316 (±5) nm, respectively.

^SThe yields of I* are 91.7 ± 0.8 , 90.1 ± 0.8 , 88.5 ± 0.8 , 84.0 ± 1.4 , 80.6 ± 1.3 , 69.0 ± 1.4 , 68.0 ± 1.5 , 62.9 ± 1.7 , 60.6 ± 1.8 , 47.4 ± 1.3 , 41.2 ± 1.3 , and $37.5\pm1.1\%$, for 275, 279, 283, 290, 293, 295, 296, 297, 298, 300, 302, and 303 nm, respectively.

 $^{T}\beta = 1.91 \pm 0.02$, 1.82 ± 0.03 , 1.70 ± 0.03 , 1.6 ± 0.05 , 1.44 ± 0.04 , 1.43 ± 0.03 , 1.43 ± 0.04 , 1.65 ± 0.05 , 1.64 ± 0.07 , 1.64 ± 0.07 , and 1.68 ± 0.05 for 275, 279, 283, 290, 293, 295, 296, 297, 298, 300, and 308 nm, respectively.

^UThe yields of I* are 71 ± 7 , 72 ± 3 , 89 ± 5 , 79 ± 3 , and $63\pm2\%$, for 222, 236, 266, 280, and 305 nm, respectively.

^VIn the photodissociation of CF₃(ν_2), the wavelength-dependent $\beta(\lambda)$ parameters are determined. The $\beta(\lambda)$ dependencies vary in the ranges 1.8–1.9, 1.8–1.94, 1.7–1.9, and 1.4–1.7 for $\nu_2=0$, 1, 2, and 3, respectively.

^WThe data of Koffend and Leone⁶⁶⁸ have been corrected by Smedley and Leone^{.669} Γ = 1.9, 5.8, 5.5, 6.8, 8.2, 8.8, 21, 23, 29, 34, 38, 36, 38, 36, 39, 43, and 44% for 332.7, 329.2, 328.0, 324.1, 321.8, 319.9, 308.7, 305.7, 299.8, 296.0, 291.6, 290.9, 287.9, 286.2, 284.4, 268.1, and 265.4 nm, respectively.

 $^{X}\beta = 1.27 \pm 0.06$, 1.32 ± 0.05 , and 1.33 ± 0.06 for 277.40, 281.73, and 304.03 nm, respectively.

^aThe photolysis wavelength λ (or the range for λ) and the yield of I* (or the range for the yields) are presented. $\Gamma \sim 0$ means "below the detection limit." ^bThe yields of I* are 46±15, 79±25, 66±13, 48±16, and 46±12% for 210–187, 187–180, 180–162, 162–158, 158–155 nm, respectively.

°The yields of I* are 68±7, 72±8, 74±9, 71±7, 71±6, 66±7, and 62±6% at 240, 250, 260, 270, 280, 286, and 290 nm, respectively.

^dThe yields of I* are 57±2, 72±2, 60±2, 39±2%, for 222, 266, 280, 305 nm, respectively.

"The yields of I* are 80±7, 78±3, 81±3, 73±2, and 52±5%, for 222, 236, 266, 280, and 305 nm, respectively.

^fHere the average yield of I* atoms over the A-band (200–350 nm) is given. The dependence of the yield on the wavelength is presented in Fig. 4 of paper of Ivanov *et al.*⁶⁰²

^gThe yields of I* are 74±7, 78±3, 97±3, 75±3, and 83±5%, for 222, 236, 266, 280, and 305 nm, respectively.

^hThis result is wrong, it was corrected by Wight and Leone.⁵⁰⁶

ⁱI* and I atoms were not distinguished.

^jThe yields of I* are 72 ± 10 , 27 ± 15 , 40 ± 10 , 49 ± 8 , and $42\pm12\%$ for 210-187, 187-180, 180-162, 162-158, 158-155 nm, respectively.

^kThe yields of I* are 67±5, 77±5, 67±5, 60±3, 58±4, and 46±3% at 240, 250, 260, 270, 280, and 290 nm, respectively.

¹The yields of I* are 68±15, 74±25, 52±10, 45±9, 49±13% for 210–187, 187–180, 180–162, 162–158, 158–155 nm, respectively.

^mThe yields of I* are 100±3, 96, 95, 92, 90, 82, 84, 75, 68, 68, 59, 44, and 40% for 265–292, 295, 298, 301, 304, 308, 312, 316, 320, 324, 328, 332, and 336 nm, respectively.

ⁿThe yields of I* are 52±7, 60±4, 71±4, 71±4, 57±4, 49±4, 36±6, and 21±3% for 247.5, 251.5, 274, 275.5, 280.5, 287.5, 296.0, 301.5, and 312.5 nm, respectively.

°The yields of I* are 79 ± 15 , 98 ± 5 , 100, 99 ± 2 , 109 ± 7 , 109 ± 9 , and $79\pm30\%$ for 234, 246, 266, 283, 299, 316, and 333 (±5) nm, respectively.

^pThe yields of I* are 87±8, 76±3, 83±2, 89±3, and 90±5%, for 222, 236, 266, 280, and 305 nm, respectively.

^aThe yields of I* are 100±3, 96, 92, 91, 85, 82, 80, 72, 61, and 75% for 265–301, 304, 308, 312, 316, 320, 324, 328, 332, and 336 nm, respectively. ^bThe yields of I* are 68±6, 64±2, 83±1, 80±3, and 89±2%, for 222, 236, 266, 280, and 305 nm, respectively.

^sThe yields of I* are 65±13, 84±5, 84, 84±3, 99±4, 98±4, and 87±25% for 234, 246, 266, 283, 299, 316, and 333, (±5) nm, respectively.

^tThe data of Pence *et al.*⁹⁴ have been corrected by Smedley and Leone:⁶⁶⁹ the yield of I* is <0.3 and 57% for 308 nm photodissociation of C₆H₅I and C₆H₅CH₂I, respectively.

^uThe yields of I* are 18±10, 82±20, 13±8, 45±8, and 25±14% for 210–187, 187–180, 180–162, 162–158, 158–155 nm, respectively.

^vThe yields of I* are 24±15, 72±20, 17±10, 53±8, and 43±8% for 210–187, 187–180, 180–162, 162–158, 158–155 nm, respectively.

"The yields of I* are 68±6, 83±3, 75±3, 80±3, 87±2%, for 222, 236, 266, 280, and 305 nm, respectively.

The yields of I are 91±22, 99±12, 88, 93±9, 93±9, 93±12, 64±15, and 109±20% for 234, 246, 266, 283, 299, 316, 333, 343, (±5) nm, respectively.

 y The yields of I* are 52±2, 57±1, 52±2, 45±1, and 42±1%, for 222, 236, 266, 280, and 304 nm, respectively.

^zThe yields of I* are 78 ± 7 , 69 ± 2 , 82 ± 2 , 74 ± 3 , $82\pm1\%$, for 222, 236, 266, 280, and 305 nm, respectively.

^AThe yields of I* are 69 ± 6 , 65 ± 3 , 70 ± 2 , 74 ± 2 , and $71\pm 3\%$ for 222, 236, 266, 280, and 305 nm, respectively.

^BThe yields of I* are 67 ± 6 , 83 ± 3 , 76 ± 2 , 75 ± 2 , $73\pm 3\%$, for 222, 236, 266, 280, and 305 nm, respectively.

^CThe yields of I* are 61±5, 44±2, 59±1, 48±4, and 42±2%, for 222, 236, 266, 280, and 305 nm, respectively.

 ${}^{3}\Pi_{1}$ state splits into the 2A" and 3A' components, and the ${}^{1}\Pi_{1}$ state splits into the 4A" and 5A' components; ${}^{3}\Pi_{0^{+}}$ becomes the 4A' state.

Brief reviews of the photodissociation of ICN have been published by Black *et al.* in 1990,^{633,688} by Amatatsu *et al.* in 1994,⁶⁸⁹ and by Costen *et al.* in 1999.¹⁵⁰

a. Experiment. The following is a brief summary of experimental information on the photodissociation of ICN.

(i) The I*/*I* branching ratio peaks at 266 nm and remains significant in the 239–290 nm wavelength.^{630,632,633,688,690} Note that the energetic threshold for forming I*+CN is 295 nm. The wavelength dependence of the ratio was measured by Hess and Leone⁶³² and by Pitts and Baronavski.⁶³⁰ The results agree near 266 nm and do not agree near 280 nm.

The I*/*I* branching ratio changes significantly with increased temperature of ICN, consistent with the increased width of the state-dependent CN rotational distribution, but the β parameter remains almost unchanged (β =0.49 at T=100 °C and β =0.58 at T=400 °C).^{151,152,691}

(ii) Rotational distributions of CN are different for I* and I channels and they change substantially with photolysis wavelength.^{152,632,633,688,690,692–698} The I* channel leads to cold CN(*N*) rotational distributions (N < 30) which are peaked at low *N*, and the I channel produces a hot CN(*N*) rotational distribution peaked at high *N* (20 < N < 60).^{152,631,699}

(iii) Vibrational excitation of CN is small.^{631,692,694,695,700,701} For example, the relative population [v=0]:[v=1]:[v=2] was found to be 0.88:0.10:0.02,⁷⁰⁰ and 0.91:0.06:0.03⁶⁹³ for photodissociation at 308 and 299.4 nm, respectively.

(iv) The anisotropy parameter β for the I* channel is higher than for the I channel.^{150,631,698,699} For example, at 266 nm, $\beta_I = 1.3 \pm 0.2$ and $\beta_{I*} = 1.6 \pm 0.2$,^{150,631} and at shorter wavelengths the difference $\beta_{I*} - \beta_I$ is even larger.¹⁵⁰

(v) Measurements of rotational alignment of CN photofragments are also reported.^{150,153,154,696,699} Low rotational states of CN display negative alignment, with the rotation axis preferentially perpendicular to the photolysis polarization, and higher rotational states have very small alignment.

In the experiments with photodissociation of ICN by circularly polarized photolysis light at 248 nm, a large net orientation of the CN angular momentum relative to the direction of laser beam has been observed.^{698,702}

(vi) The relative populations of F_1 and F_2 spin-rotation components of CN radicals show nonstatistical behavior over a wide range of rotational numbers N for both I* and I atom state exit channels.⁶³³ The populations oscillate as the CN rotational quantum numbers increase.^{695,703}

(vii) The femtosecond technique has been applied to ICN photodissociation, as a test case for femtosecond transition spectroscopy.^{704–711} From the clocking measurements it was obtained that the transition state lives for only ~50 fs, and the "dissociation" time is 205 ± 30 fs.⁷⁰⁷

b. Theory. A lot of theoretical studies on the photodissociation of ICN have been reported. Classical or semiclassical trajectory calculations,^{152,689,693,712–715} the Franck–Condon overlap model,^{716,717} infinite order sudden approximations,⁷¹⁸ time-dependent,^{719,720} and time-independent^{721–724} quantum mechanical simulations have been applied. Almost all of them assumed that two excited states contribute to the process and fail to explain the I* yield peak near 260 nm. Several authors have pointed out that at least three excited states should be taken into account.^{714,719} The contribution of the third excited state was confirmed experimentally by Black in 1993.⁶⁸⁸

Probably the most important contribution to theory is the *ab initio* potential energy surface calculated by Amatatsu, Yabushita, and Morokuma.^{689,725} Almost all calculations after 1994^{720,726-730} are based on this energy surface.

5.2.4. Photodissociation of CH₃I

Brief reviews of the photodissociation of CH_3I have been published by Johnson *et al.*⁷³¹ and by Amatatsu, Yabushita, and Morokuma.^{732,733,126,734}

There are at least five potential energy surfaces energetically accessible in the A-X band (210–350 nm). In Mulliken's notation, they are ${}^{3}Q_{2}$, ${}^{3}Q_{1}$, ${}^{3}Q_{0+}$, ${}^{3}Q_{0-}$, and ${}^{1}Q_{1}$.⁵¹⁰ Three of them are dipole allowed, the ${}^{3}Q_{0+}$ state correlates asymptotically to I* via a parallel transition, while the ${}^{3}Q_{1}$ and ${}^{1}Q_{1}$ states correlate to the I atom via a perpendicular transition

$$CH_{3}I(X,A_{1}) + h\nu \rightarrow CH_{3}I(^{3}Q_{1}2E, {}^{1}Q_{1}3E) \rightarrow CH_{3} + I,$$

$$\Delta\Omega = \pm 1, \ \beta = -1, \qquad (48a)$$

$$\rightarrow \mathrm{CH}_{3}\mathrm{I}({}^{3}\mathcal{Q}_{0}^{+}2A_{1}) \rightarrow \mathrm{CH}_{3} + \mathrm{I}^{*}, \quad \Delta \Omega = 0, \ \beta = 2.$$
(48b)

Here, A_1 and E are appropriate C_{3v} notation. The photodissociation of CH₃I is direct, single photon excitation results in a $n \rightarrow \sigma^*$ transition breaking the C–I bond in <1 ps.⁷³⁵

a. Experiment. The following is a brief summary of experimental information on the photodissociation of CH_3I .

(i) The peak component absorption wavelengths (and percentage total absorption strengths) have been determined by Gedanken and Rowe in 1975 to be 300 nm (1%), 261 nm (78%), and 240 nm (21%), for ${}^{3}Q_{1}$, ${}^{3}Q_{0+}$, and ${}^{1}Q_{1}$, respectively.¹²⁰ This decomposition analysis, based on a magnetic dichroism measurement, has served as the main guideline for many superb theoretical efforts for more than 2 decades. Contrary to this result, the contribution of the ${}^{1}Q_{1}$ and ${}^{3}Q_{1}$ states to the total *A*-band absorption spectrum were determined recently by Eppink and Parker by means of the velocity map imaging technique to be only 1.1% and 0.2%, respectively.¹⁸⁵

(ii) The I^*/I ratios are very different for different vibrational states of CH_3 .⁶⁴⁴

(iii) The vibrational distribution of the CH₃ photoproduct has been studied in many papers; of special interest is the distribution over the umbrella mode ν_2 . The long-standing consensus was that the available energy is preferentially channeled into the ν_2 mode, resulting in an inverted distribution peaked at v=2 in the dominant I*+CH₃ channel.^{128,637–639,736–740} However, more recent experimental^{185,644–646,741–746} and theoretical^{732,747–750} studies have provided contradictory evidence. The story of the revision has also been reported in several reviews.^{614,751,752}

The distribution of the CH₃ radical over vibrational modes has been probed by time-of-flight mass-spectrometry,⁶⁴⁶ REMPI,^{644,645} CH₃ velocity map imaging,^{185,753} detection of infrared emission,⁷⁴⁴ photoionization techniques, including zero kinetic energy (ZEKE),^{754–756} conventional photoelectron spectroscopy,⁷⁵⁷ and by photoelectron spectroscopy obtained from velocity map imaging.⁷⁴⁶ The yield of I* atoms depends on the vibrational state of CH₃: for example, at 266 nm photodissociation of CH₃I it is found to be 95, 89, 72, and \leq 33% for the ground vibrational state and for the $v_2=0, v_2=1, v_1=1$ vibrational states of CH₃.^{641,753}

(iv) The rotational distribution and alignment of CH_3 and CD_3 photoproducts have been determined. $^{128,645,734,753,758-760}$

(v) Note that REMPI of CH_3I may occur via different pathways. The study of Garrett *et al.* has shown that absorption in the 330–335 nm wavelength region leads to competition between nonresonant multiphoton ionization of CH_3I and single photon ionization through the *A* band.⁷⁶¹

b. Theory. A lot of theoretical studies on the photodissociation of CH₃I have been reported.⁷⁵⁰ The most often used model treats the system as a pseudotriatomic; that is, C–H bond lengths are fixed and the C_{3v} symmetry is assumed.⁷³⁷ More recent work has included two coupled dissociative potentials^{739,749,762} and more than two degrees of freedom.⁷⁴⁹ The last *ab initio* surface, which does not assume the C_{3v} symmetry is presented by Amatatsu *et al.*⁷³² Based on this new *ab initio* surface, 3D wave packet calculations were performed.^{748,749} Time-independent wave packet quantum mechanical simulation,⁷⁶³ close coupled calculations,^{737,739} classical trajectory calculations,⁷³² self-consistent eikonal approximation,^{764,765} spin-orbit *ab initio* study,⁷⁶⁶ and full quantum calculations⁷⁶² of different aspects of CH₃I photodissociation have been reported.

5.2.5. Photodissociation of CF₃I

a. Absorption band analysis. The first absorption A band (230–330 nm) of CF₃I is due to a $n \rightarrow \sigma^*$ transition and it consists of three overlapping transitions from ground ${}^{1}A_{1}$ state to ${}^{3}Q_{1}$, ${}^{3}Q_{0}$, and ${}^{1}Q_{1}$ states, similarly to the situation with photolysis of CH₃I, see processes (48a) and (48b). According to the decomposition analysis from 1987, based on a magnetic dichroism measurement, the peak component absorption wavelengths (and percentage of total absorption strengths) are 302 nm (7%), 264 nm (84%), and 238 nm (9%), for ${}^{3}Q_{1}$, ${}^{3}Q_{0+}$, and ${}^{1}Q_{1}$, respectively.⁶⁴² Furlan *et al.* have determined the wavelength-dependent β and β^* parameters and the I*/I ratios in the 275-303 nm wavelength range under cold molecular beam conditions (T=2.7 K).⁶⁶⁴ The analysis of these data includes the ${}^{3}Q_{1} \leftarrow X$ and ${}^{3}Q_{0}$ $\leftarrow X$ optical transitions and the ${}^{3}Q_{0} \rightarrow {}^{1}Q_{1}$ nonadiabatic transition. The probability of this nonadiabatic transition was found to be 0.09 at 275 nm and 0.24 at 300 nm. However, this interpretation remains qualitative mainly due to the lack

of an accurate optical absorption cross section of CF_3I at T=2.7 K.⁶⁶⁴ Similar results were obtained by Kim *et al.*;⁶⁶³ for example, the ${}^3Q_0 \rightarrow {}^1Q_1$ crossing probabilities have been found to be 0.038, 0.089, and 0.40 for the photodissociation of CFI* at 248, 277, and 208 nm, respectively.

Kavita and Das¹⁹⁶ have obtained lower values of the I*/I ratio, than the values obtained by Furlan *et al.*⁶⁶⁴ and by Kim *et al.*⁶⁶³ This was explained by the fact that the experiments of Kavita and Das were done at a much higher temperature. A strong temperature dependence of the absorption cross section was found by Felder.⁶⁶² A theory of curve crossing in photodissociation of CF₃I was presented by Clary,⁷⁶⁷ see also the recent spin-orbit *ab initio* study of Ajitha *et al.*⁷⁶⁶

b. Vibrational state distributions and energy relaxation of CF_3 . The photolysis of CF_3I at 248 nm yields mainly $I^* + CF_3$. The distribution of CF_3 over the ν_2 vibrational mode in this process has been determined recently by Wang *et al.* by TOF-MS.⁷⁶⁸

The photodissociation of CF₃I at 304 nm has been studied by Hwang and El-Sayed.⁶⁶¹ For the I* channel, a strong photon energy dependence of the CF₃ internal excitation was observed; this fact suggests strong final state interaction in the dynamics of the ${}^{3}Q_{0}$ potential as suggested by a number of model calculations. The best agreement obtained with the model calculation of van Veen *et al.*^{637,639} supports the assumption of the dominant involvement of the ν_{2} umbrella vibration.

Quack *et al.* have studied infrared multiphoton dissociation of CF_3I . Absolute rate parameters have been obtained from quantum dynamics, statistical mechanics, and the direct measurements.⁷⁶⁹

Also, Suh *et al.* have studied the energy relaxation dynamics of CF₃ fragments produced from the photodissociation of CF₃I in argon at 266 nm by means of the time-resolved probe beam deflection technique.⁷⁷⁰ The vibrational reflection principle in model calculations for photodissociation of CF₃I was presented by Schinke *et al.*⁷⁷¹

c. Formation of exciplexes. In 1982 Gerck has found that the optical I^{*}–I transition at 1.3152 μ m may be enhanced by collisions of I^{*} atoms with parent RI molecules (CF₃I, C₂F₅I, *i*-C₃F₇I, and *n*-C₃F₇I).⁷⁷² The enhancing mechanism is exciplex emission of the RI-I^{*} molecule at 1.3 μ m, with different rates for each iodide. The influence of this effect on the measurement of the quantum yields of I^{*} and of the respective reaction rates by infrared fluorescence was discussed.

5.3. Production of I* Atoms in Chemical Reactions and in *V*,*E*-*E* Energy Exchange Processes

The data for I^{*} yields from chemical reactions and energy exchange processes are presented in Table 21. Since the production of X^{*} atoms in chemical reactions has been reviewed by Dagdigian,⁵ here we just add several new references.

Trickl and Wanner have observed the bimodal IF vibrational distribution from the $F+I_2$, IBr, and ICl reactions and

Reaction	I*/(I*+I) (%)	Detection	Reference

TABLE 21. Yields of I* atoms from chemical reactions and V, E-E energy transfer processes

^aSee also experimental work of Nazar *et al.*⁷⁸⁵ and theoretical study of Dinur and Levine.⁷⁸⁶ ^bUpper limit. No I* observed.

^cAccording to Callear and Wilson, the yield of I* must be very small.⁵³¹

^dSuggestion based on the bimodal distribution of IF.

eThe rate constant is $(7.8\pm0.6)\times10^{-11}$ cm³/molecule \cdot s.^{234,565}

^fI* was detected, but the yield was not determined.

^gThe rate constant for quenching of NCl($a^{1}\Delta$) by I(²P_{3/2}) was found to be $\ge 1 \times 10^{-10}$ cm³/molecule s. It is interpreted as evidence of an efficient near-resonant energy transfer process NCl($a^{1}\Delta, v=0$)+I \rightarrow NCl($X^{3}\Sigma^{-}, v=2$)+I*.

^hThe rate constants for I+NF($b^{1}\Sigma^{+}$) \rightarrow I^{*}+NF($a^{1}\Delta$) and I+NF($b^{1}\Sigma^{+}$) \rightarrow products processes are $(3.1\pm1)\times10^{-11}$ and $(8.8\pm4.4)\times10^{-11}$ cm³/molecule·s, respectively.

proposed an explanation based on a high yield of excited I* atoms in these reactions. This explanation contradicts the direct measurements of other authors.^{515,773,774} An alternative explanation comes from quasiclassical trajectory calculations made by Urrecha *et al.*⁷⁷⁵

Also, production of I* atoms in the O+HI reaction was observed by Cadman 776 and Smith. 777

6. Different Subjects Concerning X* Atoms

6.1. X+YZ→XY+Z Reactions

Different correlation diagrams for collinear reactions of the types

$$X^*/X + YZ \rightarrow XZ + Y^*/Y, \tag{49}$$

$$X^*/X + HY \rightarrow HX + Y^*/Y, \tag{50}$$

where X, Y, and Z are halogen atoms are presented in several papers.^{5,87,443,557,558,775} These diagrams predict: (1) that $X^* + YZ(HY)$ reactants and the $Y^* + XZ(HX)$ products are adiabatically correlated via the $2^2A'$ second excited surface and suggest a barrier to this $X^* \rightarrow Y^*$ reaction and (2) that the X + YZ(HY) reactants and the Y + XZ(HX) products are also correlated via both ${}^2A'$ ground-state and excited ${}^2A''$

surfaces, the first one not having any barrier. Hence $X \rightarrow Y$ and $X^* \rightarrow Y^*$ reactions are normal adiabatic channels; the last one has a barrier and thus it normally must be much less probable than the first one. Note also, that there are not any adiabatic correlations for $X^* \rightarrow Y$ and $X \rightarrow Y^*$ pathways; moreover, even curve crossings for the appropriate nonadiabatic transitions are absent.

However, Wiesenfeld and Wolk have extended these correlation diagram to noncollinear collisions.⁴⁶⁹ It was pointed out that no activation barrier is predicted if the attack of the X* atom on the YZ molecule occurs via the side-on approach. Hence, the X* \rightarrow Y* reactions may be fast. There are two good examples for such reactions: I* + Br₂ \rightarrow Br* + IBr^{97,212,469,558} and I* + ICl \rightarrow Cl* + I₂.^{200,201}

6.2. E-V Energy Exchange

Donovan, Husain, and Stephenson⁵¹⁸ and Leone and Wodarzcyk⁴⁶² were the first to provide direct evidence for an electronic-to-vibrational E-V energy transfer mechanism, which often dominates the deactivation process. The quenching rates are particularly rapid for near resonant E-V energy transfer.^{467,468} Additionally, the E-V transfer can be mode specific.^{223,467} Vibrational distributions can be easily inverted; for example, several Br* transfer lasers have been

demonstrated.^{197,219–222} A detailed discussion of such processes is presented, for example, in the review of Houston.⁴

Two mechanisms, long-range multipolar interactions^{787,788} and nonadiabatic curve crossings789,790 have been suggested as being responsible for the E-V energy transfer. Both predict a strong correlation of the deactivation probabilities with the energy defect for the case of E-V energy exchange. Correlation plots are presented in a large number of papers.^{4,470,539,791} Sometimes these two mechanisms may be distinguished by the temperature dependence of the deactivation rate constants: while the long-range multipolar interactions lead to negative dependence $(P_{EV} \sim 1/T)$, nonadiabatic curve crossings may give negative $(\ln P_{EV} \sim 1/T^{1/2})$ or positive $(\ln P_{FV} \sim -1/T)$ dependencies, depending on the activation energy to the crossing region. Calculations based on the long-range multipolar interactions mechanism have been done for $Br^* + H_2O$, D_2O ,⁵⁴² $I^* + HF$,HCl,HBr,HI,⁵³⁹ $I^* + H_2$, D_2 , and HD,⁷⁹² $Br^* + CO_2$,⁴⁵⁹ $I^* + HBr$,⁵⁴⁴ and $O(^1D) + HCl(DCl)$.⁴⁴² The nonadiabatic curve crossings approach has been used to study the Br*+HF,HCl and $I^* + HF, HCl$ systems⁷⁹³ and $CI^* + H_2$, D_2 quenching processes.³⁴⁰ Note that a large number of more accurate quantum-mechanical studies are not mentioned here.

Several empirical relations to predict the rate constant of *E-V* exchange have been proposed.^{202,539,791} The relation proposed by Dobychin *et al.* for the $A^* + M \rightarrow A + M^*$ deactivation process seems to be one of the best:⁷⁹¹

$$k = 0.083k_0 n^{1.15} \exp\left(-0.68 \frac{\nu_A}{\nu_B} \frac{I_M}{EA_A}\right).$$
(51)

Here k is the deactivation rate constant, $k_0 = \langle \sigma_0 v \rangle$ is the gas-kinetic rate constant, n is the number of near-resonant vibrations in the M molecule or the degeneracy of vibration, I_M is the ionization potential of the M molecule, EA_A is the electron affinity of the A atom, v_A and v_B are the frequencies of the spin-orbit transition in the halogen atom, and the vibrational transition in the M molecule, respectively. This relation was used to fit a large amount of experimental rate constants, and all numerical values were obtained by the least-squares method. However, it works mainly with iodine and bromine atoms (A=Br or A=I), while the predictions for chlorine atoms very often are poor.

6.3. Pressure Induced Broadening and Frequency Shift

The pressure induced line broadening of halogen atoms X^* and X is determined first of all by the depolarization processes

$$X^*(M_J = 1/2) + A \rightarrow X^*(M'_J = -1/2) + A,$$
 (52)

$$\mathbf{X}(M_J) + \mathbf{A} \rightarrow \mathbf{X}(M'_J \neq M_J) + \mathbf{A}, \tag{53}$$

where A denotes the collision partner. While processes (52) are very slow, processes (53) are very quick. Normally they have gas-kinetic kinetic rate constants. This fact may be explained either by the theorem of Kramers, which says that

the electric field is unable to remove the twofold degeneracy in a system with odd summary spin⁷⁹⁴ or, less generally but more concretely, it was explained by Gallagher.⁷⁹⁵ Sometimes it is called the $m_j \rightarrow -m_j$ selection rule for a *j* multiplet of an atom with an odd number of electrons.^{796,797}

In other words, while process (53) occurs due to van der Waals interactions, process (52) is possible only due to Coriolis mixing of adiabatic electronic molecular states; hence it usually has low probability.⁷⁹⁸ For example, one can see rather low cross sections for EPR line broadening of F* atoms (see Table 7), Cl* atoms (<0.020 Å² for Cl* + He and <0.031 Å² for Cl* + Ar),^{155,156} and Br* atoms (<0.02 Å² for Br* + Ar).⁴⁶⁰ Note also that the depolarization cross section for Tl(²P_{1/2}) and Cs(²P_{1/2}) atoms in collisions with He and Ne atoms are 4 orders of magnitude lower than the cross section for ²P_{3/2} states of these atoms.^{797,799,800} However, when particle A has electronic momentum, depolarization processes (52) may be rather quick also.⁸⁰¹ For example, cross sections for EPR line broadening for F* + O₂ and Br* + O₂ are 5.7 Å²,¹⁵⁶ and 42 Å²,⁴⁶⁰ respectively.

As one can see from these considerations, the pressure broadening of the halogen ${}^{2}P_{1/2}$ - ${}^{2}P_{3/2}$ transition is determined mainly by the ground ${}^{2}P_{3/2}$ state. Pressure broadening coefficients for several gases are reported for the F*–F transition, 13,802 for the Cl*–Cl transition, 54,75 and for the I*–I transition, ${}^{23,803-805}$ The temperature dependence of the I*–I broadening is reported by Zagidullin *et al.*⁸⁰⁵ A quasiclassical theory of the pressure broadening is developed by Reznikov and Umanskii⁸⁰⁶ and applied to the broadening of the F*–F transition by He and Ar.

Note also that the pressure induced frequency shift in the atomic iodine laser is reported by Muchtar *et al.*⁸⁰⁷

6.4. Transitions between Hyperfine States

The transitions between hyperfine sublevels in excited X^* halogen atoms are determined by processes (52) and may also be by the depolarization of nuclear spin. To the knowledge of the author there has been only a few direct experimental determinations for the rates of the collisional relaxation in X* atoms between the hyperfine sublevels. In these studies the quick relaxation by O₂ and slow relaxation by nonparamagnetic particles was observed, in agreement with the theoretical prediction of Yukov.⁸⁰¹

Chichinin and Krasnoperov have determined the rate constant for the relaxation inside the hyperfine structure of Cl^* due to collisions with O_2

$$Cl^{*}(F=2,M_{F}=2)+O_{2}\rightarrow Cl^{*}+O_{2},$$
 (54)

 $k = (4.0 \pm 0.8) \times 10^{-12}$ cm³/molecule s.⁵⁴ In this study the Cl^{*} atoms were excited in the Cl^{*} ($F = 2, M_F = 2$) state from the ground ${}^{2}P_{3/2}$ state by the fast magnetic field jump version of the time-resolved laser magnetic resonance (LMR) technique.⁵⁴ These experiments were done in the presence of a constant magnetic field (967 G), in which the ${}^{2}P_{1/2}$ state of the Cl^{*} atom is split into eight components.

In experiments of van Marter and Heaven I* atoms were generated by 498 nm photolysis of I₂, and laser induced fluorescence (LIF VUV) was used to detect I* atoms in the F=2 and F=3 hyperfine sublevels.¹⁴⁷ The nascent population distribution of the hyperfine levels was found to be nonstatistical, with $N(F=2)/N(F=3)=1.3\pm0.1$. Collisions with O₂ caused a fast $F=2 \leftrightarrow F=3$ transfer

$$I^{*}(F=3) + O_{2} \rightleftharpoons I^{*}(F=2) + O_{2}.$$
 (55)

The analysis of F=2 and F=3 decay kinetics yielded hyperfine transfer rate constants of $k(2\rightarrow 3) = (2.6\pm 0.3) \times 10^{-11}$ and $k(3\rightarrow 2) = (1.9\pm 0.2) \times 10^{-11}$ cm³/molecule·s, both at T=150 K. Churassy *et al.* obtained an estimate of the $k(3\rightarrow 2)$ rate constant from a computational model of the iodine laser, where the value of 1×10^{-10} cm³/molecule·s has been obtained.⁸⁰⁸ A similar approach was used $[k(3\rightarrow 2)+k(2\rightarrow 3)=\sqrt{T/300}\times 10^{-10}$ cm³/molecule·s] and a similar result was obtained by Zagidullin *et al.*²⁴⁴⁻²⁴⁷ A detailed discussion on hyperfine relaxation of I* atoms in collisions with O₂ is presented by van Marter and Heaven.¹⁴⁷

Thieme and Fill analyzed the kinetics of pumping of the F=3 sublevel of I* atoms by the F=2 sublevel until equilibrium is reached; the initial nonequilibrium between these sublevels was created by a strong pulse of an iodine laser on the I* (F=3)-I(F=4) transition. Atomic iodine in the ground state was assumed to be the main relaxator. The hyperfine transfer rate constants for the process

$$I^*(F=2) + I \rightarrow I^*(F=3) + I,$$
 (56)

was determined to be $k_{23} = (1.01 \pm 0.25) \times 10^{-9}$ cm³/molecule · s.⁸⁰⁹

Also, Cerny *et al.* proposed a new way to determine the rates for hyperfine relaxation from pressure-broadening coefficients.⁸⁰⁴ For the I^*+O_2 system the result was $k(3\rightarrow 2)+k(3\rightarrow 3)=1.57\times 10^{-10}$ cm³/molecule·s, where $k(F\rightarrow F')$ is the inelastic scattering rate constant for the process $I^*(F)+O_2(J)\rightarrow I^*(F')+O_2(J')$. Note that all such rate constants $k(3\rightarrow 2)+k(3\rightarrow 3)$ were found to be gas kinetic and almost equal for many systems (I^*+Ne ,Ar,Kr,Xe,O₂). Since these values are orders of magnitude higher than the typical EPR pressure broadening coefficients for X* atoms, the interpretation of Cherny's experiment is unclear.

6.5. Picosecond Studies of Geometrically Restricted Reactions

6.5.1. Br*+l₂

A picosecond time-resolved study of the interaction of Br^{*} with I₂ has been presented by Wright, Tuchler, and McDonald.^{810,811} The electronically excited complex BrI₂ was prepared by photodissociation of the van der Waals dimer HBr · I₂ (or DBr · I₂) at 220 nm. Results show that the interaction begins on the excited potential surface Br^{*} + I₂. The originally formed excited BrI₂ complex does not have enough internal energy to dissociate directly, but must undergo an internal conversion to a lower electronic state in order to continue to reactants or products. The evolution of the complex was probed by picosecond REMPI of I atoms and I₂ molecules. Two reaction pathways have been observed: the first leads mainly to $Br(^{2}P_{3/2}) + I_{2}(v > 0)$, the second pathway leads to IBr+I.

6.5.2. I*+CO₂, OCS

The photodissociation of I_2^- at 395 nm embedded in clusters of CO₂ or OCS molecules has been studied experimentally by Sanov *et al.*⁸¹² and theoretically by Delaney *et al.*⁸¹³ and by Sanov *et al.*⁸¹⁴ The photoexcitation promotes I_2^- to a dissociative state correlating with $I^- + I^*({}^2P_{1/2})$, the only near-ultraviolet channel for unsolvated I_2^- . In $I_2^- \cdot (CO_2)_n$ and $I_2^- \cdot (OCS)_n$ clusters, interactions with the solvent are observed and result in extremely fast spin-orbit relaxation, which occurs by electron transfer from I^- to $I^*({}^2P_{1/2})$, giving $I({}^2P_{3/2}) + I^-$. The energy produced by this transition is bridged by differential solvation due to solvent asymmetry. Mechanisms of direct quenching of I^* atoms by the solvent are ruled out.

6.6. Coherent Control Theories

Quantum control theories (see study of Lu *et al.*⁸¹⁵ and references therein) propose a new and interesting way to study photodissociation processes. One of such theories was used by Lu *et al.* to stimulate the control of the relative product yield of the photodissociation of CH₃I and IBr.⁸¹⁵ The calculation shows that it is possible to vary the yields of I* atoms over the range of 26%–98% in dissociation of CH₃I and the yield of Br* atoms over 9%–94% in the dissociation of IBr. Also, coherent effects⁸¹⁶ in the photodissociation of ICN have been predicted recently by Batista and Brumer.⁸¹⁷ The I*/I branching ratio can be controlled over a broad range of values, simply by changing the relative phases of two lasers that photoexcite an initial superposition state to the same final energy state in the *A* continuum.

6.7. Heterogeneous Interactions

Muller-Markgraf and Rossi have studied the kinetics of the interaction of Cl and Cl^{*} atoms with polycrystalline nickel surfaces,⁷⁶ and the interaction of Br and Br^{*} atoms with teflon and polycrystalline nickel surfaces.⁸¹⁸ Although the sticking coefficients were found to be almost the same for ²P_{1/2} and ²P_{3/2} states of the halogen atoms, the reaction mechanisms were found to be different for these two atomic states.

Also, the rate of deactivation of I* atoms by the wall was determined by Haaland and Meyer to be $4 \times 10^{-2} (T/P)$ s⁻¹, where *P* is the pressure in Torr, and *T* is the temperature in K.¹¹⁵

6.8. Three-Body Ionic Recombination Reactions

Excited RgX* excimers play the central role in the gas excimer lasers (here Rg denotes a rare gas and X denotes a halogen atom). One of the two processes producing these excited excimers is the three-body ionic recombination reaction. The formation of RgX^* , Rg^* , and X^* , by the reactions

$$Rg(^{2}P_{1/2}, ^{2}P_{3/2})^{+} + X^{-} + He \rightarrow RgX^{*} + He,$$
 (57a)

$$\rightarrow$$
Rg*+X+He. (57b)

$$\rightarrow$$
 Rg+X*+He, (57c)

has been studied by Tsuji *et al.* by the flowing-afterglow method for the $Rg=Xe/X=Br^{819}$ and for the Rg=Ar,Kr,Xe/X=Cl systems.^{820,821} It is interesting that in the Rg=Xe/X=Br system the yield of Br* atoms is 19% for the $Xe^+(^2P_{1/2})$ state and only 0.67% for the $Xe^+(^2P_{3/2})$ state.⁸¹⁹

6.9. Photodissociation in Liquid or Solid Environment

6.9.1. Photodissociation of HI and HBr in Solid Rare Gases

Pettersson and Niemien have recently observed I^*-I and Br^*-Br transitions from the UV photolysis of HI or HBr in solid rare gases (Ar, Kr, Xe).⁸²² These absorptions consist of zero-phonon lines and of phonon side bands. Some of the zero-phonon lines are split and the phonon side bands show structures at lowest temperatures (7 K). The splitting is attributed to the atoms being in slightly different, but well defined environments.

It is interesting, that the radiative lifetimes of X^* atoms in solid gas matrices are shorter than in the gas phase; for example, the $I^* \rightarrow I$ transition has a lifetime of 0.13 s in the gas phase, and 1–5 ms in rare gas matrices.^{823–825}

6.9.2. Photodissociation of ICN in Solid Ar

The photodissociation of ICN in solid Ar has been studied experimentally (see study of Helbing and Chergui⁸²⁶ and references therein) and theoretically.^{827,828} According to the calculations of Amatatsu and Morokuma on the photolysis of ICN at 260 nm in liquid Ar at T = 100 K, out of 100 trajectories 38 are dissociative, 38 are trapped in the INC region, and 24 are trapped in the ICN region. Most dissociative trajectories (36 out of 38 above) go to the I* channel.⁸²⁸

6.9.3. Photodissociation of CH₃I Thin Films

The first study of the photolysis of CH₃I absorbed on various substrates was reported by Barker, Purnell, and Young, who observed C₂ and C₃ hydrocarbons produced in the photolysis of CH₃I films at 77 K.⁸²⁹ Dissociative desorption, photoproduct characterization, and dynamics of the photolysis of CH₃I have been studied in thin films on Ag(111) at 248 nm by Coon *et al.*,⁸³⁰ in condensed CH₃I at 266 nm,⁸³¹ and on LiF(001) and NaCl(001) at 248 nm⁸³² by Polanyi *et al.* and by Kutzner *et al.*,⁸³³ and on MgO(100) by Fairbrother *et al.*^{834,835} In all cases the yield of I* atoms was found to be smaller than it is in the gas phase (73%). For example, in thin films on Ag(111) it was 0.52±0.05 and the

yield was dependent on the film thickness.⁸³⁰ However, in thick layers the behavior of the yield is more complicated.^{833–835}

The 257 nm photochemistry of CD_3I adsorbed on MgO(100) has been investigated by Trentelman *et al.*⁸³⁶ It was found that the laser-induced desorption of methyl iodide competes with dissociation at the surface. The total cross section for removal of adsorbed CD_3I from the surface was comparable to the gas phase cross section. A significant portion of the atomic iodine fragments remain trapped at the surface with preferential trapping of I*.

6.9.4. I*-I* Contact Pair Emission in Condensed Media and in Matrices

Fluorescence spectra of molecular iodine in room temperature solutions (solvents: CS_2 , $C_2F_3Cl_3$, $CHCl_3$,...) and in cryogenic rare gas matrices (Ar, Kr, Xe, Kr/Xe; T=12-30 K) were obtained by two-photon excitation in the 500–600 nm range by Apkarian and Apkarian.⁸³⁷ The emission spectra were assigned to the dipole allowed I*I*(${}^{2}P_{1/2}$ + ${}^{2}P_{1/2}$, 0_g^+) \rightarrow I*I[${}^{2}P_{1/2}+{}^{2}P_{3/2}$, $B(0_u^+)$] transitions, that is, to pairs of spin-excited I* atoms which are strictly bound in the solvent (matrix) cage. The interaction between two excited I* atoms leads to three potentials, 0_g^+ , 0_g^- , and 1_u , which are repulsive; however, the pair of I* atoms is stabilized by the cage effect. The decay kinetics of I*I* is remarkably different in solid matrices and in liquid solutions.

In condensed media, emission of I^*I^* provides a simple and sensitive means for determining the size of the cavity in which the molecule resides. Although the spectral width of these transitions is broad, a rather accurate determination of cavity sizes, to within ± 0.1 Å, is possible in the range 8-12 Å. Also, the analysis yields a refined I*I* potential.⁸³⁷ In cryogenic matrices, the emission spectra are analyzed to characterize cage potentials and contact distances.⁸³⁸

7. Conclusions

It is believed that practically all studies on the X* atoms are mentioned in the present compilation, which is planed to be a basis for the electronic database on excited atoms. The analysis of this literature is far from being complete; attention is focused mainly on several items: the detection methods, the deactivation rate constants, the rate constants for the reactions producing X* atoms, the β parameters, and the yields of the X* atoms in the photodissociation. The author hopes that all available data of these kinds are presented here; in almost all cases the evaluation of these data may be done on the basis of this paper without reading the original literature. The author will be grateful to readers who bring to his attention publications that have been inadvertently omitted.

The weakness of this study is the shortcoming of another kind of data, the absence of recommendations and recommended values, and the absence of discussion on theoretical results. As one can see even from this paper, at the present time the contributions from molecular dynamics studies and from the theoretical studies to the understanding of processes involving X^* atoms are growing. However, these data are outside the frame of this work.

8. Acknowledgments

A. I. Chichinin is grateful for the support of the Alexander von Humboldt Foundation. Helpful discussions with C. Maul and K.-H. Gericke are also acknowledged.
